We captured 593 *T. scripta* over the course of the study, of which 423 (71.3%) exhibited a biting response (Table 1). The stepwise logistic regression removed melanism as a significant predictor of biting response in adult males and indicated that plastron length predicted propensity to bite. However, melanistic individuals were significantly larger than nonmelanistic individuals ($F = 259.8$, $P < 0.001$). Therefore, we ran a logistic regression using plastron length alone for adult males and plastron length was a significant predictor of biting response ($P < 0.001$, Odds Ratio = 1.028). Although Chi-square contingency analysis indicated that melanistic and partially melanistic males are more likely to bite than nonmelanistic males ($\chi^2 = 9.85$, df = 1, $P = 0.0017$), the logistic regression suggests that their higher propensity to bite is related to body-size differences. Logistic regression also indicated that plastron length was a significant predictor of biting response for all turtles combined, nonmelanistic males, all females, all juveniles, and juvenile females (Table 2). Fig. 1 shows the increase in biting attempts as plastron length increased for all turtles combined. In addition to *P*-values, Table 2 includes three other methods for determining the goodness-of-fit for a logistic regression model. In determining goodness-of-fit, a good model will show that the Odds Ratio Confidence Interval should not include the value of 1 and should have a narrow range, % concordance should be large (the closer to 100% the better), and area under the Receiver Operating Characteristic (ROC) curve should be large (the closer to 1 the better). The *P*-values corresponded with values for these other methods. For example, the most significant *P*-value of <0.0001, for all turtles combined, corresponded to the highest % concordance and area under the ROC curve.

Discussion

We tested two hypotheses about biting in Red-eared Sliders: 1) body size is a significant predictor of propensity to bite; 2) degree of melanism in males is a significant predictor of propensity to bite. These hypotheses were not mutually exclusive because degree of melanism was correlated with body size as reported by Lovich et al. (1990). Therefore, the effect of body size on propensity to bite had to be accounted for before the effect of melanism could be properly evaluated.

Our results supported the body-size hypothesis. Using logistic regression, we demonstrated a strong relationship between body size and biting. In the Red-eared Slider, biting propensity increases with an increase in body size in juveniles, females, and nonmelanistic males, groups in which melanism is not a factor. This seems to indicate that regardless of other factors, such as sex and melanism, body size is the predictor of biting. Bite force increases with increasing body size in many species of turtles (Herrel et al. 2002). Therefore, biting should be a more effective defensive strategy in larger turtles. Conversely, smaller turtles might be better off keeping their head retracted, even in species that lack plastral hinges, such as red-eared sliders.

Our results did not support the melanism hypothesis. Using logistic regression, the effects of melanism on bite propensity were not significant. The evolution of melanism in Red-eared Sliders has been widely discussed (Lovich et al. 1990; McCoy 1966; Thomas 2002; Tucker et al. 1995). In general, interest has preceded data (see Thomas 2002), producing a surplus of hypotheses that have remained mostly untested (Lovich et al. 1990). In particular, the hypothesis that melanism evolved via sexual selection has a number of untested or anecdotal components, including the assertion that melanistic males are more aggressive than non-melanistic males (Cagle 1950; Cahn 1937; Carr 1952; Lardie 1983; Parker 1990; Tucker et al. 1995). Our data suggest that any differences in aggressive behavior between melanistic and non-melanistic males are the result of differences in body size.

We recorded biting attempts toward a human observer instead of attempting to observe intrasexual aggression. Many reports of increased aggression in melanistic males are based on observations involving turtles and human observers (Cagle 1950; Cahn 1937; Carr 1952; Mafli et al. 2011; Tucker et al. 1995;). While this may validate our experimental design, it seems clear that making observations of interactions between conspecifics of different sizes and degrees of melanism in a natural setting would be preferred. Most progress in sexual selection theory has been made using animal models that are easy to observe in nature such as fish, lizards, and birds (reviewed in Andersson 1994). Less is known about behavior and social systems of freshwater turtles because they often live in turbid water, making direct observations difficult. Instead, speculation often prevails, such as we have addressed herein. The behavior of freshwater turtles is likely to be interesting, but advancing our knowledge in this area will likely require carefully designed experiments rather than anecdotal observations coupled with speculation.

Body Size and Sex Ratio in a Population of Spotted Turtles (*Clemmys guttata*) in Southwestern Michigan

Body size within populations of reptiles can vary as a function of age, genetics, sex, and random variation in resource acquisition among individuals (Andrews 1982; Gibbons and Lovich 1990). Within freshwater turtle populations, body size distributions show a preponderance of large adults due to either low recruitment (Browne and Hecnar 2007) or sampling methods that favor the collection of adults relative to juveniles (Ream and Ream 1966; Reeves and Litzgus 2008). Among populations, differences in mean, minimum, and maximum body sizes may be influenced by variation in environmental factors such as diet, primary productivity, and climatic factors that affect environmental temperature and growing season length (Iverson 1992; Iverson and Smith 1993). Among populations of some species of freshwater turtles for example, mean population body size (carapace length or mass) and some measures of reproductive output (e.g., clutch size) are positively correlated with longitude, latitude, or both (*Chelydra serpentina*, Iverson 1992; Iverson et. al. 1997; *Chrysemys picta*, Iverson and Smith 1993). Relatively large body size at more northern latitudes (Bergmann's Rule) may be related to heat retention (Ashton and Feldman 2003; Mayr 1963) or to enhanced energy acquisition and storage for

growth or reproduction in a seasonal environment (Iverson and Smith 1993; Iverson et al. 1993; Olalla-Tárraga et al. 2006; Rollinson and Brooks 2007).

Sex ratios skewed toward either sex can result from intersexual differences in natality, mortality, or maturation schedules in freshwater turtles (Gibbons 1990; Lovich and Gibbons 1990; Lovich et al. 1990). Skewed operational sex ratios could impact reproductive output and thus population growth rate because members of the more abundant sex may have limited access to mating opportunities (Fisher 1930). Variation in primary sex ratio (sex ratio at hatching) can be related to a bias in nest thermal conditions that favor the development of one sex or through temperature-dependent sex determination (Gibbons 1990; Lovich and Gibbons 1990). Intersexual differences in seasonal movement patterns (nesting forays by females and overland travel by males for mating purposes) can lead to skewed secondary sex ratios if individuals experience differential mortality rates while terrestrial (Aresco 2005; Gibbons 1990; Gibbs and Steen 2005; Lovich and Gibbons 1990). Age at maturity can impact secondary sex ratio if members of one sex mature before those of the other sex (Georges et al. 2006; Gibbons 1990). For instance, because males do not carry eggs, maturation at the

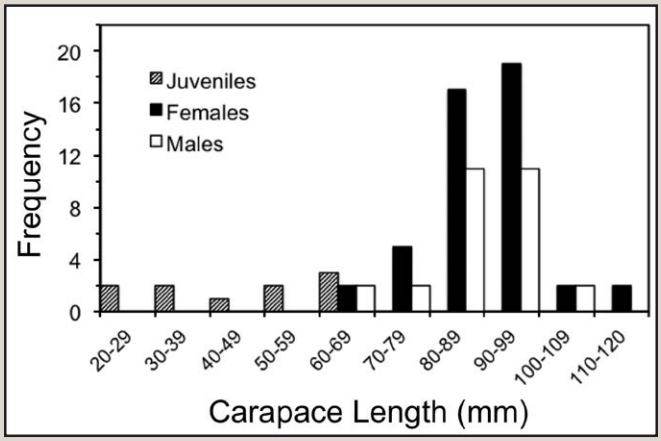

FIG. 1. Body size frequency distributions of juveniles (N = 10), adult female (N = 47), and adult male (N = 28) *Clemmys guttata* from southwestern Michigan, 2004–2007.

smallest size possible for successful reproduction can lead to male-biased secondary sex ratios (Dunham and Gibbons 1990; Lovich and Gibbons 1990).

The Spotted Turtle (*Clemmys guttata*) is widely, but discontinuously, distributed over a range of latitudes that span eastern North America as far south as Florida, USA, and as far north as southeastern Ontario, Canada (Ernst and Lovich 2009). *Clemmys guttata* occupies a range of habitats including various shallow wetlands and uplands (Litzgus and Brooks 2000) and coupled with its broad distribution, local and latitudinal body-size variation among populations would be expected. Mean population body size is positively, but weakly, correlated with latitude and may actually be intermediate at more intermediate latitudes (Litzgus et al. 2004), which could reflect a trade-off between growth and body size and clutch frequency (Litzgus and Mousseau 2006). In order to clearly understand broad-scale geographic variation in body size of *C. guttata* given the substantial variation in mean population body size within a region (Litzgus and Brooks 1998a; Litzgus et al. 2004), a comprehensive documentation of body-size variation throughout the distribution will be critical. Sex ratios are either equal or female-biased in *C. guttata* (Reeves and Litzgus 2008; Seburn 2003) and potential causes of skewed sex ratios include nest-site selection biases that cause differential production of females through temperature-dependent sex determination (Schwanz et al. 2010) or differential mortality and longevity of the sexes (Litzgus 2006; Martins and Souza 2009).

We studied body-size variation and sex ratio in a *C. guttata* population in southwestern Michigan. A paucity of life-history information has been reported for *C. guttata* from Michigan and few data have been reported from the northwestern part of the species' range. If body size is correlated with latitude (Litzgus and Brooks 1998a), then we expected that mean body size (carapace length and body mass) should be relatively large given the northern location of our population. We expected a 1:1 secondary sex ratio because there is no indication that nest-site selection is related to the determination of sex through temperature-dependent sex determination in *C. guttata* (Lovich and Gibbons 1990). Although female longevity may exceed that of males in some *C. guttata* populations (Litzgus 2006; Seburn 2003), the turtles of our study population reside in a single wetland year-round (Rowe et al., *in press*) and elevated mortality that occurs during long-distance treks for nesting or mate seeking should be minimal and result in a secondary sex ratio of parity.

Materials and methods.—Our study site is a 14-ha wetland in southwestern Michigan, USA (42°N, 85°W; elev. 228 m) that is dominated by grasses (chiefly *Spartina pectinata* and *Eriophorum virginicum*), sedges (*Carex* spp.), Leather Leaf (*Chamaedaphne calyculata*), various ferns (chiefly *Matteuccia struthiopteris* and *Pteridium aquilinum*), and *Sphagnum* sp. mounds and bordered on all sides by Tamarack (*Larix laricina*) and White Cedar (*Thuja occidentalis*) swamp (see Rowe et al. *in press* for a more detailed site description). Between May and August of 2004–2007 and 2009, we searched the study site and located turtles as they were aquatically active in deer trails or in depressions, or when they were terrestrial on vegetation. We measured maximum straight-line carapace length (CL) to the nearest 1 mm using calipers (50 cm, Haglöf aluminum tree caliper, Långsele, Sweden) and body mass (BM, g) using spring scales (100 g, Pesola, Kapuskasing, Ontario, Canada). Because male and female *C. guttata* mature at similar ages and sizes (Litzgus and Brooks 1998a), we considered individuals that lacked male secondary sex characteristics (concave plastron and relatively long pre-cloacal tail length) and that had CL values that were equal to, or exceeded, that of the smallest identifiable male (65 mm) to be adult females (Ernst and Lovich 2009). We included morphometric measurements only from the initial capture of an individual to maintain statistical independence. We uniquely marked individuals by shell notching (Cagle 1939) and released them at their capture sites within several hours.

Results and discussion.—A majority of individuals in the population were adults, with females being more numerous than males. We captured 85 turtles of which 10 were juveniles (12%), 47 (55%) were females, and 28 (33%) were males (Fig. 1). Similarly, throughout the range of *C. guttata*, juveniles and adults averaged 16% (9–28%) and 82% (73–91%) of the total population, respectively (N = 5, populations 4–5 and 6–9 in Table 1). While a small percentage of juveniles might suggest low recruitment (Ernst 1976), hatchlings and relatively small juvenile turtles may be difficult to find (Reeves and Litzgus 2008) or occupy microhabitats that are different from those of adults (Congdon et al. 1992). However, we found both juveniles and hatchlings within the boundaries of our study site. It therefore seems probable that if more than 50% of female *C. guttata* reproduce nearly annually (Litzgus and Mousseau 2006), hatchlings and larger juveniles would have been more frequently collected if juvenile survivorship were high.

In contrast to our prediction, we did not find that average body size was relatively large in our population of *C. guttata* that is in the northern part of its distribution (Litzgus and Brooks 1998a) and at a relatively high latitude (Iverson 1992; Iverson and Smith 1993). In fact, mean CL values for female (88.2 mm) and male (87.5 mm) *Clemmys guttata* of our northern population were near the lower range of values reported for populations throughout the species' range (female: mean = 105.1 ± 2.4 mm, 92–115 mm; male: mean = 107.1 ± 3.3 mm, 86–116 mm; N = 8 populations 2–9 in Table 1). Similarly, Litzgus et al. (2004) found mean population CL values of near 100 mm throughout most of the range of *C. guttata* except at approximately 39°N where it declined to between 90 and 100 mm.

When we incorporated our data with previously studied populations of *C. guttata* (N = 9, populations 2–10 in Table 1), Spearman-rank correlations indicated that neither CL nor BM was correlated with latitude within either sex or for both sexes combined ($P > 0.05$). Similarly, Litzgus et al. (2004) found a weak correlation between body size and latitude only when a very

northern and large-bodied population was included in their data set. Positive correlations between latitude and mean population body size are well established among populations within freshwater turtle species (*Chrysemys picta*, Iverson and Smith 1993; *Chelydra serpentina*, Iverson et al. 1997; *Clemmys muhlenbergii*, Lovich et al. 1998; *Emys orbicularis*, Zuffi et al. 1999) and among freshwater turtle species (Iverson 1992; Iverson et al. 1993). Rapid seasonal growth in northern populations relative to southern populations seems likely to be related to delayed sexual maturation or compensatory rapid individual growth rate in an environment with low annual primary production and short growing seasons (Iverson 1992; Iverson and Smith 1993). While it is possible that latitude positively affects growth rate and body size in *C. guttata*, its relatively small body size coupled with local variations in environmental conditions (see below) that affect growth might have obscured statistically significant correlations.

Variation in habitat quality is likely to influence both turtle density (Reeves and Litzgus 2008) and individual growth rate, ultimately causing variation in mean body size among populations of *C. guttata*. Litzgus and Brooks (1998a) reported that age and size (PL) at maturity vary among *C. guttata* populations (female mean = 78.8 mm, 72–88 mm; male mean = 78.8 mm, 70–80 mm; N = 4 populations). Within populations, age and size at maturity can vary among individuals within the sexes (Ernst and Lovich 2009) but age and size at maturity appear to be similar between the sexes in *C. guttata* (Litzgus and Brooks 1998a). Interestingly, Litzgus and Brooks (1998a) found that age and size at maturity and mean and maximum body size in an Ontario population exceeded values reported from more southern populations. Delayed sexual maturation and large mean body size may increase clutch size and mass when the growing season is relatively short, such that multiple annual clutches, or even annual clutch production, are constrained (Litzgus and Brooks 1998b; Litzgus and Mousseau 2006). Minimum adult body size in our relatively northern population, at least for males for whom sexual maturity was readily discernible (CL = 65 mm, PL = 48 mm), seems well below values reported for other populations (Litzgus and Brooks 1998a). Assuming approximately similar age and size at maturity between the sexes in our population (Litzgus and Brooks 1998a), it seems likely that small mean body size was at least in part related to relatively small body size at maturity (Dunham and Gibbons 1990). At 40°N in Pennsylvania, Ernst (1970) reported minimum sizes at maturity of 81 and 83 mm for females and males, respectively, and mean PL values of 90 and 86 mm, respectively (from Ernst 1976 as estimated by Litzgus and Brooks 1998a). At our slightly more northern latitude (42°N), our comparatively small mean, minimum, and maximum PL values (Table 1) further support our conclusion that local conditions probably affect growth rates regardless of latitude and that maturation at a small body size affects mean population body size.

We suggest that individual growth and body size in our population could be seasonally limited moreso than in some other previously studied populations of *C. guttata*. A radiotelemetric study of *C. guttata* at our site indicated that turtles estivated between late June and early August and did not move to distant, more favorable habitats to continue feeding during drought (Rowe et al., *in press*); this annual period of aphagia may have resulted in overall smaller body sizes. Across the distribution of *C. guttata*, mean population clutch size and egg size are positively correlated with maternal body size and therefore with latitude (Litzgus and Mousseau 2006). Relatively small turtles at intermediate latitudes (ca. 39°N; Litzgus et al. 2004) could reflect a transition zone between turtles in southern populations that show relatively rapid pre-maturation growth with the production of one or more annual clutches and turtles in more northern populations that invest in rapid pre-maturation growth at a cost of producing one or fewer annual clutches (Litzgus and Mousseau 2006; Litzgus et al. 2004). Our small mean population body sizes indicate that local variation in life-history traits is not yet completely understood in *C. guttata*. It would be interesting to know if annual clutch frequency in our small-bodied *C. guttata* population is similar to that of turtles in populations within the "transition zone" as proposed by (Litzgus et al. 2004).

In our population, sex ratio was significantly skewed in favor of females (1 M : 1.7 F; $\chi^2_1 = 4.8$, $P < 0.05$). Similarly, female-biased sex ratios have been reported from other *C. guttata* populations (Table 1) and, with our data included, average 1 M : 2.1 F.

Differential adult mortality is the likely cause of our biased sex ratio, as alternative explanations seem inapplicable to our population. Because *C. guttata* have temperature-dependent sex determination, a female hatchling bias might be the result of warm temperatures during incubation (Ewert and Nelson 1991; Gibbons 1990). Female-biased sex ratios that result from latitudinal variation in environmental temperatures seem unlikely because female-biased sex ratios occur at northern latitudes where incubation temperatures are cooler and equal sex ratios occur at southern latitudes where incubation temperatures are warmer (Litzgus and Mousseau 2004). Reeves and Litzgus (2008) discounted differences in incubation conditions as a source of sex ratio bias between two local *C. guttata* populations because nesting conditions appeared to be identical at both of the Ontario sites. Differences in activity, movement, and habitat use patterns between the sexes (Litzgus and Brooks 2000) could lead to collecting biases or intersexual differences in mortality rates (Gibbons and Lovich 1990; Reeves and Litzgus 2008). However, because radio-tagged *C. guttata* in our population remained within a single wetland year-round and members of both sexes estivated in synchrony (Rowe et al. in press), sampling biases that are related to differential activity (Ernst and Zug 1994; Gibbons and Lovich 1990) or road mortality (Gibbs and Steen 2005) should have been minimal.

Litzgus (2006) found that females may live 1.7 times longer than males in an Ontario population, perhaps because males expend relatively large amounts of energy or experience elevated exposure to predators as they search for widely-dispersed females during the mating season (Morreale et al. 1984). Differential mortality between the sexes following sexual maturation seems the likely cause of the sex ratio bias in our population because the frequencies of each sex are fairly similar in the smallest age class but diverge through the midrange size classes (Fig. 1). However, the necessary assumptions that *C. guttata* age and size are correlated (Ernst 1975; Litzgus and Brooks 1998a) and that age-specific mortality rates of each sex are constant over the lifetimes of the individuals, both of which may change over time (Browne and Hecnar 2007), remain to be tested in our population.

Acknowledgments.—We thank C. Hanaburgh of the Michigan Department of Natural Resources and M. Skedgell and Pierce Cedar Creek Institute for logistic support. The study was conducted within the guidelines approved by the Alma College IACUC. Turtles were collected under the Michigan Department of Natural Resources and Environment Scientific Collector's Permit-Threatened and Endangered Species Permit #1581.

Reproductive Behavior of *Anotheca spinosa* (Anura: Hylidae) Under Natural Conditions in Costa Rica

Anotheca spinosa (Steindachner 1864) is a medium-sized casqued-headed frog inhabiting mainly undisturbed areas in premontane rainforests from Mexico to Panama (Savage 2002). Despite being described almost 150 years ago, the breeding behavior of this species in nature is poorly known. Tadpoles have been reported from inside bromeliads (Taylor 1954), water-filled tree holes (Duellman 2001; Robinson 1961), and bamboo (Jungfer 1996). Most information on the breeding biology of *A. spinosa* is derived from individuals found in nature and then raised in captivity (Jungfer 1996; Savage 2002), and all the information available on the breeding behavior of the species to date comes from a single report (Jungfer 1996).

Herein, we present new information on the breeding behavior of *A. spinosa* in nature, providing data on the size of egg masses, tadpole feeding habits and growth, and the male advertisement call. To our knowledge, this is the first report of the reproduction of *A. spinosa* under natural conditions.

Materials and Methods

Observations were made from May to August 2006 in a 7-ha organic coffee farm surrounded by cattle pastures and coffee plantations in Cartago, Costa Rica (9.8423°N, 83.8503°W; elev. 1300 m). The nearest town was 1 km away. Along the edges of streams at the site are small patches of secondary-growth forest. The section of the coffee plantation where the observations were made is ca. 1300 m^2, next to a dirt road and surrounded by a living fence composed of native and some introduced plant species (e.g., conifers). The number of days between visits varied so we refer to each visit by the number of days after the first visit.

We made observations of egg masses, tadpoles, and adults. Eggs and tadpoles were observed in bromeliads from 0 to 1.5 m above the ground. We counted the number of visible eggs attached to the bromeliad leaf and floating in the water in the leaf axils. If tadpoles were present, we counted them and staged all or one of them according to Gosner (1960) using a 20x magnifying glass. We determined whether tadpoles had been eating eggs by looking for eggs in their guts since we could see through their skin. We measured the snout–vent length (SVL) of adults, except for individuals found in amplexus. For individual identification we used overall phenotypic patterns. When we found a male calling, we recorded the call with a portable cassette recorder (Marantz PMD222) and a Telinga Parabola with a Sennheiser ME66 microphone. Advertisement call analyses were performed in RAVEN 1.2 (Charif et al. 2004), using a fast Fourier transformation length of 512 samples, Hann window, and 90% overlap.

Results and Discussion

Breeding behavior.—On 21 May 2006 at around 1930 h, a pair of *A. spinosa* was found in amplexus, laying eggs on a bromeliad 70 cm above the ground. Both individuals were immersed in the water tank of the leaf axil with their heads facing upwards (Fig. 1). The behavior of the pair in amplexus, submerged in the water, is partially consistent with observations described for individuals in captivity (Jungfer 1996) except that the pair we found had their heads out of water rather than underwater. The male left the bromeliad two hours later, and the female remained immersed in the water for another three hours. We could not tell if the eggs were laid that day or days before, but based on our later observations it is very probable that they were laid that night. Eggs were floating on the water and attached to the leaf. At the same time there were other two males calling simultaneously, providing evidence of at least three males and one female in the area.

Advertisement call.—We recorded the call of the three males, but we only located one (SVL 70 mm, 21.5 g), which was found twice during subsequent visits within an area of ca. 90 m^2. This male was calling early at night (1900 h) from a bromeliad leaf axil full of water (water temperature 18°C), 45 cm above the ground. Our observations of males calling from water-filled bromeliad axils coincide with the information reported by Savage (2002). The male's call consisted of a singly pulsed note repeated at a regular interval (Fig. 2). The lengths of calling bouts varied among bouts within individual males and among males. Males usually began calling with short bouts, increasing the duration over the night. Pulse duration ranged from 0.102 to 0.161 sec with an inter-pulse interval between 0.46 and 0.25 sec. The fastest-paced call had 1.88 pulses/sec. Each calling bout was separated by a pause lasting from three to five min. The calling bouts of two males ranged from 107 to 480 pulses (2–168 pulses), and lasted between 54 and 234 sec. Pulse peak frequency varied along the duration of the call, with lower peak frequencies at the beginning of the call, ca. 375 Hz up to 560 Hz. When harmonics were present, the dominant frequency was found in the first harmonic. The calls usually began at a very low intensity, barely audible to the human ear, and continued rising in intensity until they could easily be heard from more than 100 m away. The calling activity of the other two males lasted for 45 min and two hours each.

Tadpole development and survival.—We located only four bromeliads occupied by tadpoles, adults, or both. The maximum number of eggs observed in a leaf axil was 166; the minimum number of tadpoles found in a leaf axil was three. For those axils where less than five tadpoles were found, we were not able to locate them in subsequent visits.

FIG. 1. *Anotheca spinosa* pair in amplexus and eggs.

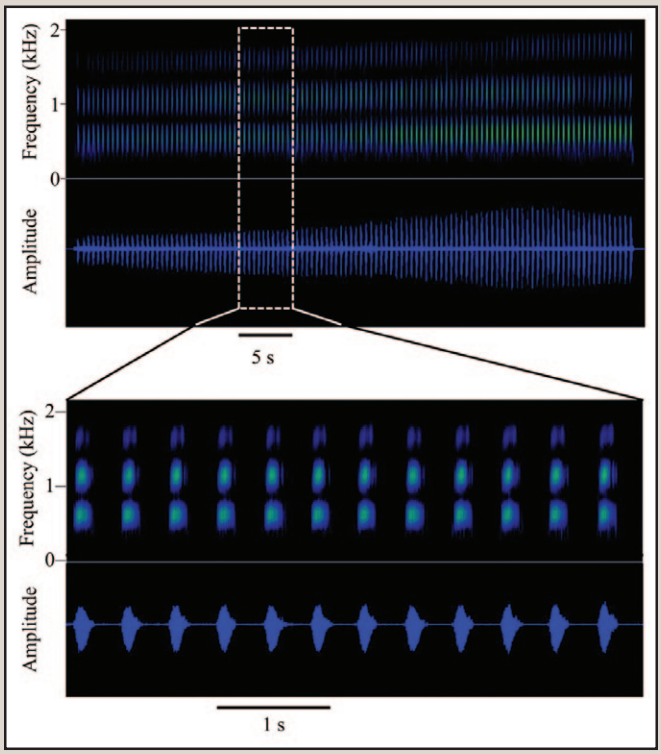

FIG. 2. Spectrogram and oscillogram of the call of a male of *Anotheca spinosa* recorded at 18°C.

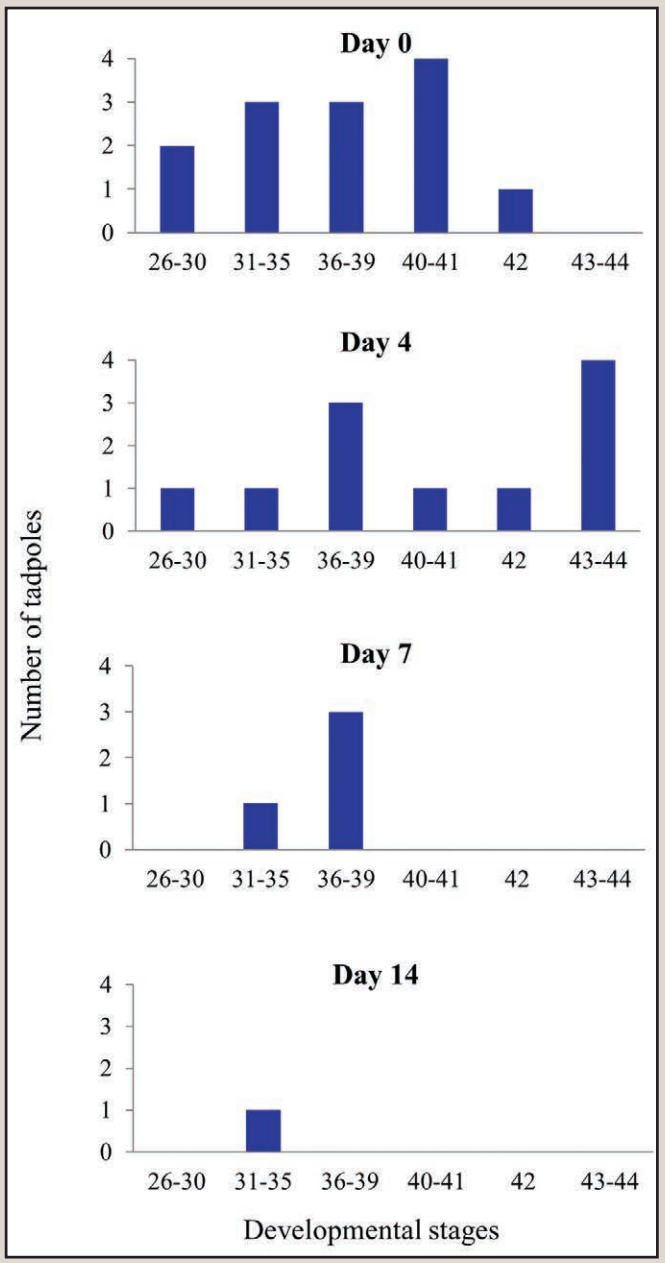

FIG. 3. Number of tadpoles by Gosner (1960) developmental stages found in a single leaf axil over time.

One week after we observed the pair in amplexus there were 35 tadpoles in the same axil; two and three weeks after oviposition only two tadpoles remained in the leaf axil. To avoid the possibility that disturbance may compromise their development, we did not measure these tadpoles, but we could observe they had not reached the stage when hind legs are noticeable (stage 36). In another bromeliad, we observed 13 tadpoles between stage 26 and 42 (Gosner 1960). Fourteen days after the first visit only one tadpole at stage 31–35 remained in this bromeliad (Fig. 3)

CONCLUSIONS

Jungfer (1996) described *A. spinosa* amplexing late at night and laying eggs during the day, while we found a pair of *A. spinosa* in amplexus early in the night, with the female already having laid eggs. As we did not record the starting time of the amplexus, it is possible that this pair may have been in amplexus since the previous night. At our study site, the number of eggs and tadpoles varied greatly among bromeliads; Jungfer (1996) reported similar information from different regions. Our study found the largest number of *A. spinosa* tadpoles in a single axil (N = 35) reported in nature to date. This number is also higher than the maximum number of tadpoles hatched in captivity so far.

Anotheca spinosa is classified as Near Threatened (NT) on the IUCN Red List due primarily to habitat loss over much of its range (Santos-Barrera et al. 2004). During the last revision of this list in 2004, the species was reclassified to Least Concern (LC) largely due to anecdotal reports of this species in disturbed areas. The fact that we found this species in a highly disturbed area near a busy dirt road, and reproducing in a bromeliad in

front of a house supports that this species is able to breed in disturbed areas. More data on recruitment success and long-term population trends are necessary.

Acknowledgments.—We thank Ernest Carman and Ernesto Carman Jr. for their hospitality and permission to access and conduct fieldwork on their farm. We thank Gilbert Barrantes, James. V. Remsen, Carlos Guarnizo, Sabrina Amador, and Michael J. Ryan for their valuable comments and revision of the manuscript.

Spectral Analysis Reveals Limited Potential for Enhanced-Wavelength Detection of Invasive Snakes

Effective control of invasive species often requires novel and multifaceted approaches. A comprehensive approach to the control of invasive Brown Treesnakes (*Boiga irregularis*) on Guam includes trapping (Rodda et al. 1999; Tyrrell et al. 2009), application of toxicants (Savarie et al. 2001), olfactory detection by dogs (Savidge et al. 2011), and visual detection by human searchers (Christy et al. 2010; Rodda and Fritts 1992). While visual searching far surpasses trapping in successfully targeting all size classes of snakes (Rodda et al. 2007), it is not cost effective to implement in large-scale control efforts due to high labor demands and inherently low detectability of these cryptic snakes (Christy et al. 2010). Technologies that significantly and cost-effectively increase the detectability of snakes by human searchers may be welcome additions to a comprehensive toolbox for invasive species research and management.

Though the coloration of invasive snakes to the unaided human eye may be cryptic and not easily distinguished from the surrounding habitat, it has been hypothesized that detection could be facilitated by selectively filtering or amplifying portions of the visible light spectrum or converting invisible infrared or ultraviolet wavelengths in to high-contrast visible proxy images (as is done by night vision goggles). Such novel applications of advanced technologies have inherent appeal, but should be thoroughly vetted before significant investment of scarce resources. Thorough vetting of proposed control technologies reduces the likelihood of investment in projects with limited potential for success, and may redirect the allocation of resources toward lines of research that are more likely to bear fruit and be cost-effective.

Spectroscopy is the study of light as a function of wavelength. Objects reflect light differently at varying wavelengths. Variation in reflectance within the visible range of the electromagnetic spectrum is how we perceive color; however, objects also vary in how they reflect light at wavelengths beyond those we can perceive with the human eye, such as in the ultraviolet and infra-red wavelengths (see Fig. 1). An object's reflectance of electromagnetic radiation as a function of wavelength is known as a "spectral profile." In comparing objects, marked differences between their spectral profiles provide the contrast that can be used to differentiate between them.

Our objective was to determine whether the spectrum profiles of Brown Treesnakes exhibit any absorptions in reflectance which may be exploited to increase our ability to distinguish them from surrounding vegetation. If such spectral features exist within the visible range of the spectrum, we might increase an observer's chance of sighting a snake by preferentially filtering or supplementing light at key wavelengths through filtered lenses or light sources. Should such features be found in the non-visible ultraviolet or infrared domains, potential may exist for developing technologies which use sensors responsive to the targeted wavelength and translate the signal to a high-contrast visible image.

Materials and Methods.—To assess whether Brown Treesnakes have any spectral reflectance features that might be exploited in order to increase our ability to detect snakes in surrounding vegetation, we used an ultraviolet-near infrared (UV-NIR) field spectrometer to characterize the spectral profiles of dorsal, lateral and ventral surfaces of six captive Brown Treesnakes collected from Guam. Laboratory reflectance measurements were made with an ASD Inc. Fieldspec® Full Range Spectrometer over the wavelength range from 0.35–2.5 microns using a halogen lamp

for illumination and Spectralon® panel for reference. These spectra were converted to absolute reflectance using a NIST traceable spectralon reflectance spectrum. The ASD spectrometer has 5-nm spectral resolution from 0.35–1.0 microns and 11-nm spectral resolution from 1.0–2.5 microns. Snakes were measured while they were held within the beam of the tungsten lamp about 1 m distant from the light source. The ASD fiber optic probe was held perpendicular to the skin surface and 10 six-second spectra were collected at each location on the snake's body. These ten spectra were co-averaged and converted to absolute reflectance for comparison of skin absorption features. Snake spectra were plotted against reference spectra for woody and leafy vegetation and examined for wavelengths of marked contrast (Fig. 2).

Ideally, we hoped to identify one or more wavelengths at which Brown Treesnakes exhibit a peak of reflectance with respect to other objects in their environment (primarily woody and leafy vegetation). Spectra were also recorded from a Common House Gecko (*Hemidactylus frenatus*) and a Mangrove Monitor (*Varanus indicus*) as these species may also be encountered during Brown Treesnake surveys. Additionally, we took this opportunity to determine whether diagnostic absorption features existed for a Brown Treesnake (*Boiga irregularis*) from Indonesia, a closely-related Mangrove Snake (*Boiga dendrophila*), a Western Hognose Snake (*Heterodon nasicus*), and a Massasauga (*Sistrurus catenatus*). This methodology provides a high-resolution spectrum profile for the entire range of wavelengths investigated. It is not proposed as a field application for snake detection, but rather to identify a small subset of wavelengths which could be selectively filtered or amplified with equipment designed for field detection.

Results and Discussion.—Sample spectra from the ventral, lateral, and dorsal surfaces of a single Brown Treesnake specimen are plotted against reference spectra from woody and leafy vegetation in Fig. 2, while the range of all spectra from three surfaces of six Brown Treesnakes are depicted in Fig. 3. The only range within which Brown Treesnake reflectance exceeds the reflectance of vegetation is the ventral surface of the snake across the visible range of the spectrum. High reflectance across the visible spectrum is seen as white. This will be no surprise to experienced Brown Treesnake surveyors whose search image is typically triggered by the white to whitish-yellow underbelly of snakes perched in arboreal activity. The low reflectance of blues, moderate reflectance of greens and higher reflectance of reds in all body surfaces are perceived as the olive-brown color characteristic of Brown Treesnakes, increasing in darkness from ventral to lateral to dorsal surfaces. The lateral and ventral surfaces of Brown Treesnakes are

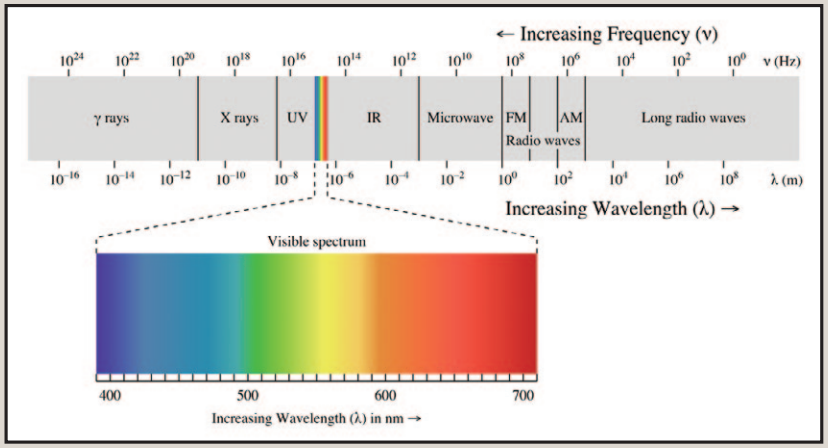

FIG. 1. Electromagnetic spectrum (© Wikimedia Commons, reproduced under the GNU Free Documentation License). The visible portion of the spectrum is from approximately 400–700 nm, or 0.4–0.7 microns.

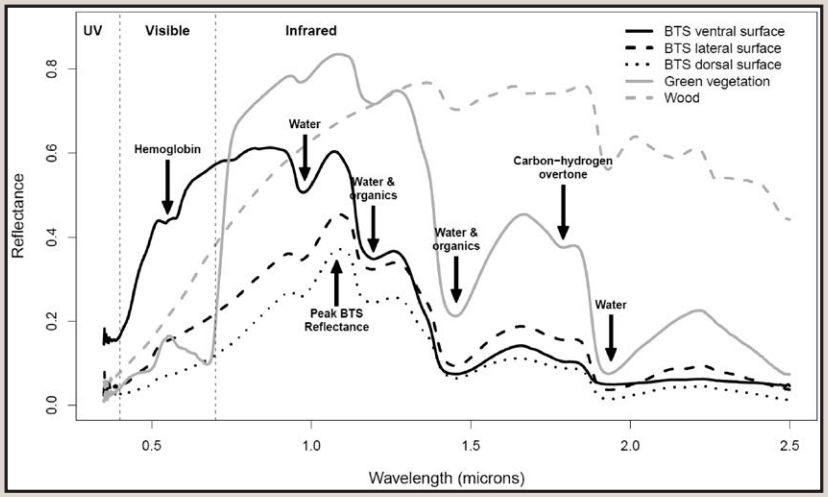

FIG. 2. Plot of spectral reflectance profiles of dorsal, lateral, and ventral surfaces of one Brown Treesnake (BTS) specimen against reference spectra from woody and leafy vegetation. Arrows highlight notable spectral features.

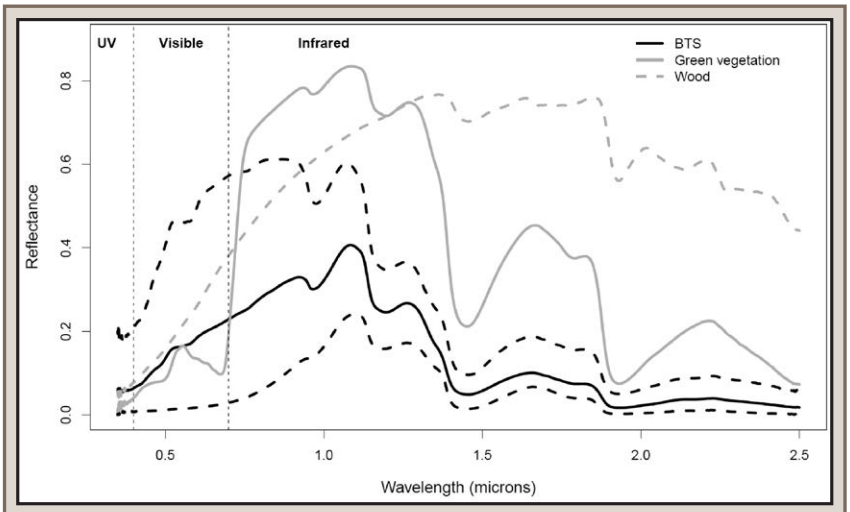

FIG. 3. Spectral reflectance profiles showing the mean (solid black), maximum and minimum reflectance (dashed black lines) from all surfaces (dorsal, lateral, ventral) of six Brown Treesnakes (BTS) against vegetation reference spectra.

as or less reflective than vegetation, requiring observers to rely upon the snake shape aspects of their search image.

While there is a large contrast between lateral and ventral surfaces of Brown Treesnakes and green vegetation in the red range (~0.7 microns), this is also true of woody vegetation. Selective filtering of non-reds or amplification of reds may help to decrease the brightness of green vegetation, but do little to distinguish snakes from the branches and vines which they also resemble in shape.

Within the span of UV wavelengths, the ventral surface of the Brown Treesnake is brighter than dorsal and lateral surfaces of the snake and the vegetation spectra; however, the magnitude of the difference is not much greater than the difference throughout the visible portion of the spectrum and overall UV reflectance is low, indicating that selective enhancement of UV wavelengths is not likely to be worth the additional technological effort required to do so.

Within the infrared domain, all three Brown Treesnake surfaces show a reflectance peak at 1.1 microns (Fig. 2); however, the chlorophyll in leafy vegetation is known to have remarkably high reflectance within the near-infrared, which overwhelms the peaks of Brown Treesnake reflectance and negates any visibility advantages these peaks might have conferred. Nowhere throughout the Brown Treesnake spectra are the hoped-for diagnostic absorptions that would have indicated promising features for selective amplification leading to the desired high-contrast search image and increased detection probability. Using a computerized algorithm exploiting the "shoulderness" of the snake's spectrum as it slopes downward from 1.1 to 1.6 microns, combined with the green peak and chlorophyll absorptions of green vegetation, one could effectively differentiate snakes from dry vegetation (which has "small shoulderness"—flat or shallow slope—from 1.1 to 1.6 microns) and green vegetation (with "large shoulderness," or steep slope) compared to intermediate shoulderness or slope of the snakes' spectra. This assumes that the spatial resolution of the image is fine enough that single pixels would land entirely on the snake. The presence of a chlorophyll band would eliminate the green vegetation while a low shoulderness would eliminate dry vegetation (branches, etc.). Collecting such spectral data at night would pose a challenge, considering the amount of light needed to get a workable signal-to-noise ratio on the detectors. While this may technically be possible, the prospects for cost-effectively implementing such sophisticated technology in a manner practical for use by a field worker are not promising.

The reference vegetation spectra were obtained in North America rather than Guam; however, given the lack of distinctive spectral features in the snake spectrum profiles, there is little reason to believe that Guam's vegetation would be different in any meaningful manner. The results of our lab experiment have indicated that a more expensive effort in Guam is not likely to be worth the investment of resources.

In comparison to the sympatric gecko and monitor species, as well as the four additional snake species tested, all spectra were similar in the UV and IR ranges of the spectrum. Given the taxonomic breadth of species examined here, it is not promising that such features may be observed in other reptile species of invasion concern, such as the Burmese Python (*Python molurus bivittatus*) and other large-bodied boids devastating the native fauna of the Florida Everglades (Dorcas et al. 2012; Dove et al. 2011). All living organisms—including vegetation—exhibit the negative spectral features, or light absorption bands, indicated at ~0.97, 1.20, 1.45, and 1.95 microns which result from absorption by water and/or the carbon-hydrogen and nitrogen-hydrogen bonds of organic compounds (Fig. 2). The ubiquity of these features in biotic organisms negates their utility as characters to discern them from other life forms. All noteworthy differences between Brown Treesnake and other reptile spectra assessed here lie within the visible portion of the spectrum, manifesting in differences in color that are obvious to the unaided eye.

As predators that rely on stealthy foraging or ambush to obtain prey, it is not surprising that the coloration of the Brown Treesnake is difficult to visually distinguish from its surroundings. The results of spectroscopy reflect little potential for simple filtering or single-feature amplification techniques. While there may be some potential for multi-wavelength computer algorithms to enhance snake features while "backing out" characteristic features of vegetation, such technologies are not likely to be cost-effective or practical for field applications in the short term. The apparent lack of significant results reported here is extremely important, in that this small-scale validation of a novel concept has forestalled a hasty investment of scarce resources in a more comprehensive research and development program, and provides important information for others considering similar approaches.

Acknowledgments.—We thank Robert N. Reed for assistance with manuscript review. All animals used during this experiment were held at the lab of Stephen Mackessy, University of Northern Colorado, Greeley, Colorado, under UNC IACUC approval (protocols 0901C & 0702). Use of an Infrared Thermographic Camera to Measure Field Body Temperatures of Small Lacertid Lizards

Measuring body temperature is crucial in the study of reptiles, as most of their behaviors and physiological processes depend critically on temperature (Angilletta et al. 2002). Different devices have been used to measure deep body temperature in lizards, including mercury thermometers, thermistors, and thermocouples. However, these devices require the use of invasive and considerably stressful techniques for lizards (Avery 1982; Hare et al. 2007; Langkilde and Shine 2006; Moore et al. 1991). Consequently, remote sensing equipments, such as infrared (IR) thermometers, are increasingly used as a non-invasive alternative to measure body temperature of reptiles in the field (Alberts and Grant 1997; Bucklin et al. 2010; Hare et al. 2007). This equipment is inexpensive, lightweight, and easy to use. However, IR thermometers are problematic when used to measure the surface temperature of small-sized animals. This is because the size of the sensing field often exceeds the surface area of the target body, so temperature readings reflect a composite measure of the target animal and the surrounding substrate (Bucklin et al. 2010; Hare et al. 2007). Thermographic cameras offer a potential alternative that may alleviate this problem.

Thermographic cameras are available to measure surface temperature (T°s) and provide several advantages over other non-invasive methodologies: 1) readings can be taken at distances ranging from a few centimeters to several meters; 2) IR images provide data on the temperature of the animal distinct from its immediate surroundings; 3) depending on the measuring distance and the resolution of the camera, it may be possible to obtain simultaneous readings from several points on the body surface of the focal lizard; 4) moving animals can be easily tracked; and 5) it is generally possible to make adjustments (e.g., correcting for emissivity) after the image is collected. Furthermore, modern IR cameras are portable, relatively cheap, and have higher image resolution than the cumbersome first-generation cameras used until recently in herpetological studies (Jones and Avery 1989; Tosini and Avery 1993, 1996).

One potential drawback of thermographic cameras and other remote-sensing equipment is that they provide a measure of surface temperature, while many behavioral and physiological processes arguably depend on deep body temperature (Angilletta et al. 2002). In small ectothermic animals, deep body temperatures should not differ markedly from body surface temperatures (Bell 1980; Jones and Avery 1989; Tosini and Avery 1993), but it is still important to understand and acknowledge the error committed. In this paper, we evaluate the use of an IR camera to estimate deep body temperatures in small lacertid lizards (adult body weight <10 g).

Materials and methods.—We collected thermographic data from five species of small lacertids: *Podarcis liolepis, Po. muralis, Psammodromus algirus, Ps. Hispanicus*, and *Acanthodactylus erythrurus*. Lizards were captured in Valencia (Spain), except for *P. muralis*, which were captured in the eastern Pyrenees (Angoustrine, France). In the laboratory, lizards were housed individually in holding terraria measuring 40 × 20 × 15 cm. Water was provided *ad libitum* while food (mealworm larvae) was provided every two days. Immediately before each test, lizards were weighed and measured (snout–vent length, SVL). During the experiment, each lizard was placed in a small experimental terrarium (20 × 15 × 15 cm) with a thermocouple probe inserted in its cloaca, and restrained under a 125W infrared spotlight (Exoterra IR lamp) that was initially turned off. The thermocouple probe was connected to a quick-reading thermometer (Omega HH96/T, ± 0.1°C) and provided an estimate of deep (core) body temperature (T°b). Ambient temperature in the test area was constantly monitored with a mercury thermometer placed next to the experimental terrarium while lizard body surface temperatures were recorded with a still IR camera (Fluke Ti25). According to manufacturer specifications, this camera has a thermal sensitivity of ≤ 0.09–30°C (90 mK) and a spatial resolution of the thermal image of 320 × 240 pixels. When room and lizard surface temperatures were similar (± 0.5°C) the lamp was turned on and the lizard was allowed to warm until the temperature of its dorsal surface reached 39–40°C, after which time the lamp was turned off and the lizard was left to cool down in the terrarium. To determine the relationship between T°s and T°b, we measured both temperatures simultaneously at one-minute intervals. Finally, we measured operative temperature (i.e., the predicted equilibrium temperature of a nonregulating ectotherm) inside the experimental terrarium with a thermocouple probe inserted into a hollow copper model measuring 64 mm length x 16 mm Ø (Hertz et al. 1993).

TABLE 1. Body mass, snout–vent length (SVL), and mean and standard deviation of the difference between dorsal surface temperature (T°s) and deep body (i.e., cloacal) temperature (T°b) when lizards were warming and cooling for the five species used in this study.

Species	N	Body mass (g) mean [range]	SVL (mm) mean[range]	Warming T°s-T°b ± SD	Cooling T°s-T°b ± SD
Psammodromus algirus	10	6.86 [5.9–9.8]	64.54 [65–74]	1.78 ± 0.48	0.38 ± 0.29
Psammodromus hispanicus	8	1.91 [1.4–1.7]	44.50 [37–46]	1.44 ± 0.46	0.76 ± 0.29
Podarcis muralis	6	6.20 [6.5–9.4]	61.83 [61–71]	1.00 ± 0.40	0.52 ± 0.30
Podarcis liolepis	10	3.28 [2.0–5.7]	52.90 [47–64]	1.34 ± 0.37	1.15 ± 0.45
Acanthodactylus erythrurus	10	8.71 [6.1–11.0]	68.30 [61–71]	1.76 ± 0.92	0.52 ± 0.30

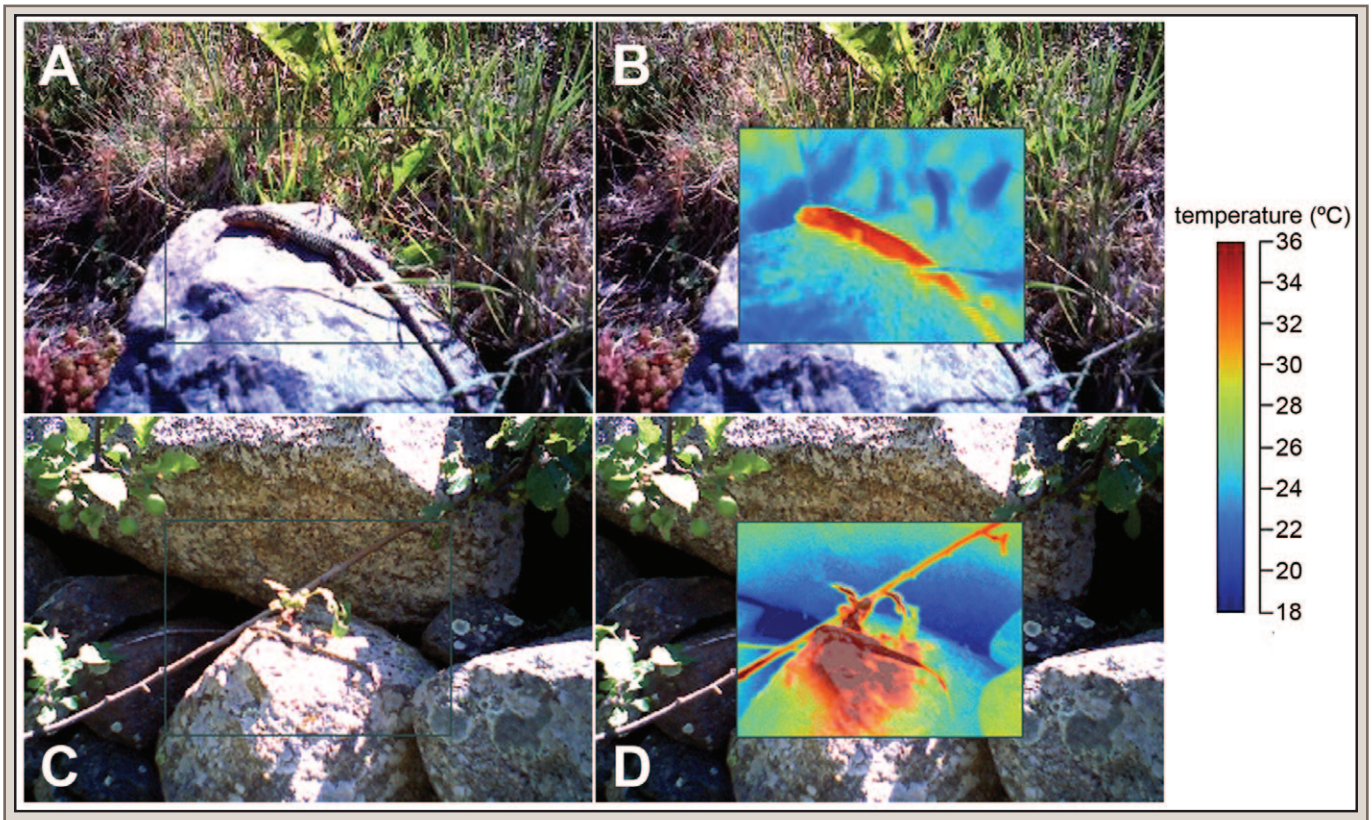

FIG. 1. A standard color digital photograph (A) and the corresponding infrared image (B) of an adult male of *Podarcis muralis* basking in the field. Digital photograph (C) and the infrared image (D) of another adult male in thermal equilibrium. In both cases, digital and infrared images were taken simultaneously with the IR camera. Note the difference in temperature between different lizard body regions (e.g. head, legs, tail). The color scale on the right indicates the surface temperature of the lizard and its immediate surroundings.

It is generally accepted that, regardless of their color, reptiles radiate almost as black bodies with an emissivity of approximately 0.95–1.00 (Carroll et al. 2005). Therefore, for acquisition of thermographic images we set the IR camera emissivity at 0.97. During preliminary trials, we determined that temperature readings varied in the range of ± 0.5°C when emissivity was varied from 0.95 to 1.00. Thermographic images were analyzed using the software provided with the camera (SmartView 2.1, Fluke), which allowed average and maximum-minimum temperature measurements to be determined from a rectangular area approximately equidistant from the insertion of the fore and hind limbs.

We plotted graphs showing variation of T°s and T°b with time when lizards were warming and cooling. To assess the relationship between T°s and T°b we also calculated determination coefficients of the two temperatures using standardized major axis regression (SMA) with (S)MATR software (v.2 Falster et al. 2006).

Results.—Fig. 1 shows two examples of the types of images produced by the IR camera. Fig. 2 presents results for each species showing variation of temperature with time**.** When the lizards were warming, the average error committed estimating T°b from IR images was 1.46 ± 0.53°C (mean ± SD) while the error committed when lizards were cooling was 0.67 ± 0.33°C (see Table 1 for further details). Determination coefficients of the relationship between T°s and T°b ranged from 0.95 to 0.99. This suggests that, in all cases, over 95% percent of the variation in surface temperature can be explained by the correlation between cloacal and surface temperatures.

Discussion.—The present study demonstrates that IR cameras can provide accurate estimates of deep body temperatures of small lizards without the need to capture or chase them. The error committed when estimating T°s and T°b should not be large in small animals due to rapid heat conduction from surface to the body core (Dzialowoski and O'Conner 2001; Seebacher and Shine

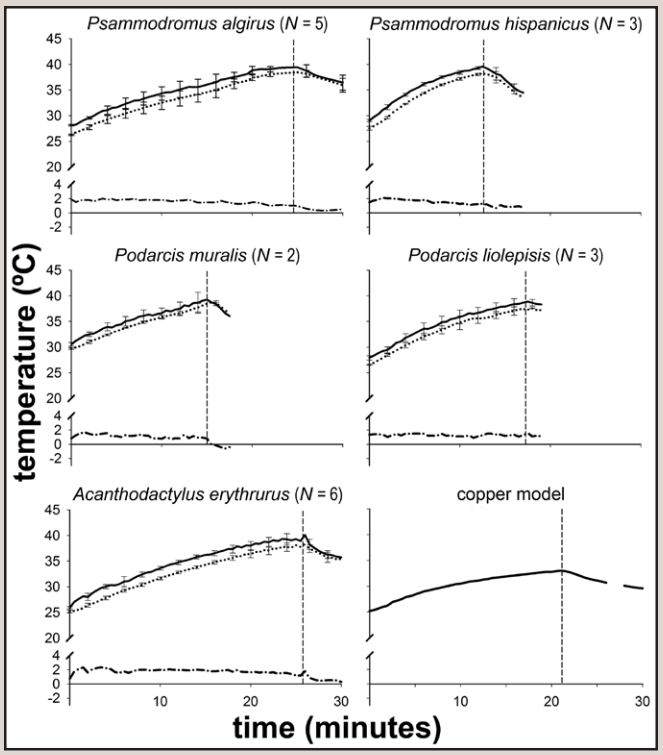

FIG. 2. Graphs showing temperature variation in five lacertid species and a hollow copper model equipped with a thermocouple probe and subject to the same treatment as the experimental lizards. Solid lines represent surface body temperature as determined from IR camera measurements. Dotted lines represent cloacal temperatures obtained by means of a thermocouple attached to a quick-reading thermometer. Differences between surface and deep body temperature are shown by dash-dot lines. The time when the spotlight was turned off is indicated by vertical dashed lines. Note that the sample sizes given differ from those in Table 1 because we have excluded from the graphs some lizards that changed location underneath the spotlight during the experiment causing oscillations in the recorded temperatures. Error bars = ± 1 SD.

2004), as shown in Fig. 2, where the lines representing T°s and T°b variation are roughly parallel and with nearly the same differential across temperatures and lizard species. The large determination coefficients between T°s and T°b ($R^2 > 0.95$) for all the species in our sample corroborate this conclusion. However, we caution that the error committed when estimating deep body temperatures of larger animals with slower rates of heating and cooling will likely be larger and should be determined empirically.

The average difference between T°b and T°s measured from an IR image when animals are basking is 1.46 ± 0.53°C, which is larger than that reported in previous studies (Jones and Avery 1989; Tosini and Avery 1993). However, this error is likely much smaller than the error committed when measuring cloacal temperatures in the field using standard procedures (Avery 1982; Hare et al. 2007). Moreover, when lizards are cooling the average error committed is 0.67 ± 0.33°C, which is similar to the error committed with other non-invasive techniques such as IR thermometers (Alberts and Grant 1997; Bucklin et al. 2010; but see Carretero 2012).

The discrepancies between T°s and T°b are possible because the dorsal skin of basking animals warms faster and may reach higher temperatures than the body core when animals are warming, and because the body core has a higher thermal inertia than the body surface when the animals are cooling (Remmert 1985; Tosini and Avery 1993). The lag between surface and core body temperature, especially during the warming phase of the experiment, reflects a lack of thermal equilibrium which may produce inaccuracies in T°b estimation (Dzialowoski and O'Conner 2001; Seebacher and Shine 2004). Although the error committed in estimating T°b from T°s is bound to be negligible in small animals with low thermal inertia, care should be taken when recording temperatures of lizards that have just started basking or that have recently moved into a new thermal environment and therefore may have not yet reached a steady state.

In conclusion, thermographic cameras are a useful alternative to traditional techniques for measuring body temperature in small reptiles in the laboratory and in the field. Our results demonstrate that, at least for small lizards, thermographic cameras can provide precise and highly accurate estimates of deep body temperature. Although thermographic cameras have several advantages over other non-invasive techniques, perhaps the most important are the ability to simultaneously record thermal data from different parts of the lizard and its surroundings (Fig. 1), and the possibility of acquiring readings from animals at distances large enough to ensure that observer effects are minimal.

Modification of Camera Traps for the Study of Ectothermic Vertebrates

Camera traps have been used extensively to study animal behavior and ecology (Rowcliffe and Carbone 2008). Recent studies have instituted motion-sensitive camera traps as a method for noninvasive observation of crocodilian behavior (Chenna et al. 2010). However, because these devices are designed to capture images of mammals, the motion sensors on virtually all commercially available cameras are based on infrared energy detection. This presents a problem for the use of these devices for the study of ectothermic vertebrates. Recent data (not shown) collected in our outdoor alligator handling facilities have shown that, while capturing some photos of alligators, these digital camera traps are unreliable due to the fact that temperature differentials between the animal and the environment are often too small to trigger the camera's IR sensor. To resolve this problem, we designed a small electronic circuit that drives an infrared light-emitting diode (IR LED). The circuit, which is powered by tandem 9V batteries, activates the LED for two sec every five min. The IR LED is nestled against the IR detector of the camera and, when stimulated by the circuit, triggers the camera to take a photograph. Therefore, the cameras are stimulated to capture an image approximately every five min, or when triggered by another IR source (endotherm, etc.). We have used this method to monitor nests and to determine the frequency, length of time, and time of day of visits by alligators and by potential predators to nests of alligators.

Materials and Methods

Materials.—Four IR2 game cameras (Wildgame Innovations, Grand Prairie, Texas, USA) were purchased at a local sporting goods store. Plastic dry boxes, 555 timers, capacitors, resistors, and infrared LEDs were purchased from Radio Shack. Nickel-metal hydride rechargeable batteries (C and 9V), and battery charges were purchased from Tenergy Corp. (Fremont, California, USA).

Electronic Circuits.—The camera was triggered by an infrared LED which was controlled by a 555 timer circuit (Figs. 1A, B). It is one of the typical applications of the 555 timer chip. This circuit

utilizes the "astable" mode of the 555 timer, so that it continuously generates pulses whose duty cycle (percentage of time on during a periodic cycle) is controlled by a combination of resistors and capacitors. A diode was added between pins 6 and 7 of the timer such that the duty cycle was less than 50%. The 555 timer should be TTL type, as a TTL 555 chip is able to output 200 mA current which is high enough to power the IR LED. A CMOS type 555 timer should be avoided due to its limited current output

One of the resistors (R3, 330 kΩ) was used to control the length of the time interval between the periods when the IR LED was powered on (Fig. 1A). The resistance can be changed to stimulate the camera to capture images at different time intervals. The other resistor (R2, 3.3 kΩ) was used to control the amount of time which the LED was on (Fig. 1A). This value was chosen to ensure that the LED was on long enough to stimulate the camera to capture an image. Because power consumption of the circuit was a major concern, we used a 555 timer, which requires a 5 to 15 V power supply. We used three 9V Energizer batteries in parallel, which was sufficient to power the camera system for approximately 10–11 days.

The circuit was placed inside of an electrical project box to prevent corrosion from moisture in the field. A hole was drilled in the box so that the LED, in contact with the camera, could be wired into the circuit (Fig. 2A). Prior to placement in the field, the seam at the box/lid interface was sealed with electrical tape to act as a further moisture barrier. The circuit was conjugated to an electrical jack and mounted in the box such that batteries driving the circuit could be changed easily in the field without opening the electrical box.

Placement of Cameras.—Cameras were set at alligator nests in the Lost Lake area of the Salt Bayou Unit of JD Murphree Wildlife Management Area in Port Arthur, Texas, USA. For each, a metal stake was driven in the ground approximately 1.5–2.0 m from the nest, and the camera attached to the stake, approximately 0.3–0.4 m above ground level using bungee cords (Fig. 2B). The dry box containing the electrical circuit board was attached above the camera using electrical tape. The LED leads were taped to the camera such that IR light source was touching and pointed directly into the IR detector of the camera. Due to limited battery life, and storage capacity of the 2-gigabyte memory cards, batteries and memory cards were changed weekly.

Results

We employed four cameras in the field at alligator nests in June 2010. These modified cameras proved to be a reliable method for the capture of time-lapse images of both endothermic and ectothermic vertebrates. Cameras were placed such that the entire nest area was within the field of view of the camera (Fig. 2B, Fig. 3). Analysis of time stamps revealed that cameras captured images on a regular basis (every 4.5 min) throughout the week. In addition to the regular capture of images stimulated by the IR LED, the presence of endothermic animals in the area of the nests, such as mammals and birds, also triggered the camera independent of the added circuit.

Fig. 3 shows an alligator attending a nest. This series of photographs was captured during an 18-min period. From the times on the photographs, we deduced that this female alligator was at the nest site between 18 and 27 min. For instance, the minimum time (18 min) would be the possibility if the alligator arrived at the nest just as the camera was triggered, and left just after the fifth photo, thus spending the minimum time possible during the time frame. The other extreme (27 min) would be possible if the alligator arrived approximately 4–4.5 min prior to the first photo, and the left approximately 4.5 min after the fifth photo, just prior to another timed photo.

Discussion

In recent years, the qualities of commercially available camera traps have improved immensely, and costs have declined, making this technology a popular tool for the non-invasive study of animal behavior. Digital camera traps are now available from a

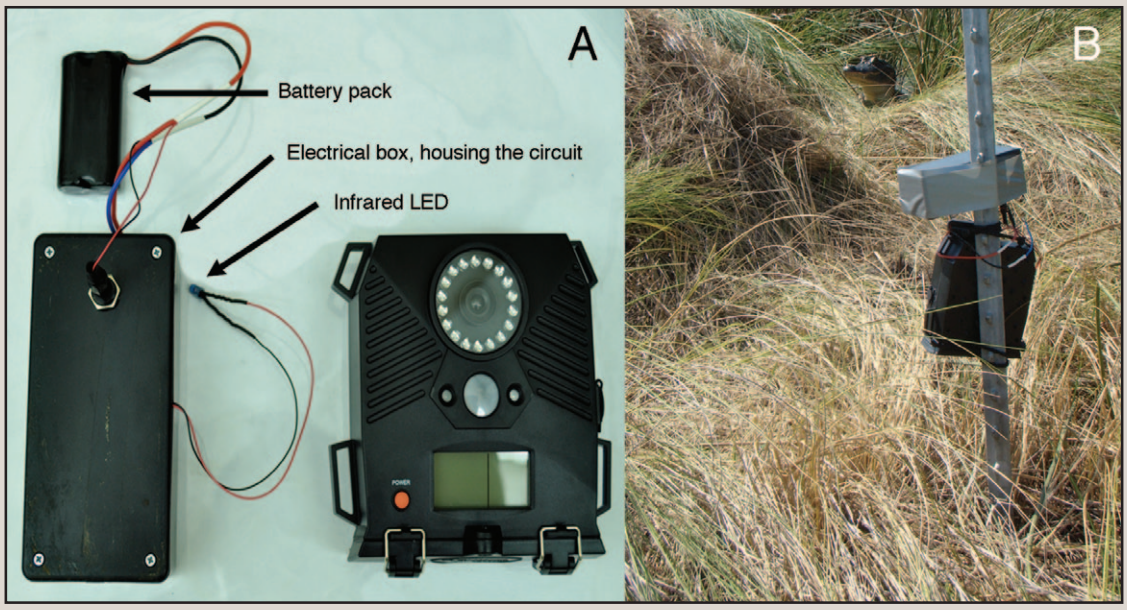

Fig. 2. A) Equipment used to capture alligator nest visitation. The IR LED light source is placed in contact with, and pointing directly into, the IR detector on the camera. The electrical circuit board is secured in the dry box to protect it from corrosion in the field. B) Placement of the camera at an alligator nest. When possible, the camera was placed to capture trails leading from the water to the nest as well.

FIG. 3. Images of an alligator captured by camera traps at an alligator nest. Since the length of time between photos is known, an approximate length of the visit to the nest can be estimated.

infrared or visible light flash, color or gray-scale photos, a variety of resolutions, and video or still-photo modes.

Camera traps are typically used to capture images of nocturnal animals, where they are commonly placed along heavily-used trails or in areas where the animals of interest are known to inhabit. Because all currently available camera traps sense motion based on infrared input, most of the studies in which these tools are used are focused on mammals. These devices have been used extensively to study of populations of feline species including tigers (Karanth 1995; Kuranth et al. 2006; Wegg et al. 2004), jaguars (Soisalo and Cavalcanti 2006), and ocelots (Maffei et al. 2005; Trolle and Kery 2000). Some studies have focused on the accuracy of using camera traps, comparing the data collected from these devices to other classical population determination techniques, such as line transect census and track surveys (Ross et al. 2003; Royle et al. 2009; Silveira et al. 2003). All of these studies and reviews have validated the use of this method for population determinations (Swann et al. 2011).

The results from the work reported here illustrate a simple modification of commercially available field cameras for the capture of images of ectothermic vertebrates. This modification is inexpensive, relatively easy, non-invasive, and provides reliable data concerning crocodilian nesting behavior. The circuits are composed of common, inexpensive electrical components; the total cost of each circuit/box was approximately US $12. Each camera was purchased for US $70, the rechargeable batteries (two sets each) for both the camera (four C) and the circuit (three 9V) were approximately US $28, and the battery recharger was US $15. Therefore, each complete camera system cost approximately US $125.

The use of these modified camera traps can provide data such as time of nest visits, frequency of visits, length of stays, and other behavioral data including egg deposition and nest opening. In addition, the time-lapse nature of the system provides a temporal aspect to the behavioral data collected. One potential disadvantage of this method is the large number of photos generated (approximately 2300 images per week), many of which may contain no useful information. However, we found that it was easy to quickly scan the images and save photographs with images of alligators at the nest. Another disadvantage is the fact that the large number of photographs means that the batteries, for both the camera and the circuit board, must be changed regularly. The batteries used for these studies provided power for approximately 10 days.

These modified camera traps will be a useful tool for monitoring the nest defense strategies of alligators and other crocodilians, and they provide a new means to study the behaviors of other poikilotherms as well. The 377 kΩ resistor used here can be replaced with another resistor of lesser or greater resistance to trigger the camera less or more frequently, respectively. The 3.3 kΩ resistor can be altered to provide a shorter or longer IR pulse, depending on the sensitivity of the camera used. Additional batteries and SD cards with larger data storage capacities can be used so that fewer trips to the field are required to replace batteries and collect photographs from the cards. Thus, with slight adjustments, this method can be adapted to meet the needs of a variety of specific research projects.

A Method for Telemetry-based Logging of Animal Activity

Using direct visual observations to collect data on the circadian rhythm of animals is tedious at best, and may be impossible if the subject moves through a habitat that prevents a clear line of sight without the observer approaching so close that data are compromised. Radio transmitters for animal telemetry can be built to incorporate a mercury switch that causes the signal to change from a fast pulse rate to a slow pulse rate depending on how the transmitter is oriented (Burger 1988). Commercially available data loggers can sit in the field and record when the transmitter changes orientation, indicating that the animal moved or changed its posture. But the lack of signal change is not evidence that the animal did not move, because not all movements cause the switch to tip (Dorcas and Peterson 2012). Whether the switch tips depends not only on the animal's body position but also on a combination of how the switch is oriented in the transmitter and the transmitter's orientation in (or on) the animal. Here we describe a method for increasing the reliability of information on animal activity and movements that can be gained from telemetry signals. We used a digital recorder to record the received signal, and then analyzed the sound files for changes in not only pulse rate (a.k.a. inter-pulse interval) but also the amplitude of the signal received at an antenna-receiver-recorder station. We exploited the fact that the transmitter's antenna orientation relative to the receiving antenna affects the strength of the signal received. The structure and density of vegetation between the transmittered animal and the receiver also cause variation in received signal amplitude as an animal travels through a heterogeneous habitat.

Methods.—We studied activity and movements in juvenile Brown Treesnakes (*Boiga irregularis*), which are almost exclusively nocturnal and to a large extent arboreal. We quietly approached snakes as they foraged in trees at night and offered them, from forceps on a 1-m stick, dead geckos containing a 1.0-g tip-switch transmitter featuring a coiled helical antenna (BD-2NHXP; Holohil Systems Ltd., Carp, Ontario, Canada). If a snake consumed the gecko, we slowly backed off. This hands-off approach left us with a snake whose movements and activity would presumably closely resemble that of an un-manipulated snake. Snakes typically passed the transmitter 5–7 days later. The smallest snakes were often wary of accepting the offered baits, so as a complementary approach we captured and hand-fed some small snakes. To minimize the risk that a snake's behavior would be affected by a feeling of satiation caused by a bulky transmitter sitting in its stomach, we had the transmitters built so that the mercury switch added to the transmitter length (31 mm including switch and antenna spool) rather than its width (6 × 4 mm where widest). The switch was incorporated so that the unstable tipping point occurred when the transmitter was positioned horizontally (i.e., lying down), as this was deemed the orientation that would result in the most tipping events.

After a snake ingested a transmitter, and every afternoon thereafter, we rigged a small, directional antenna (RA-14; Telonics Inc., Mesa, Arizona) in a tree typically 20–40 m from the snake and connected it to a receiver (R-1000; Communications Specialists Inc., Orange, California) to which was connected a

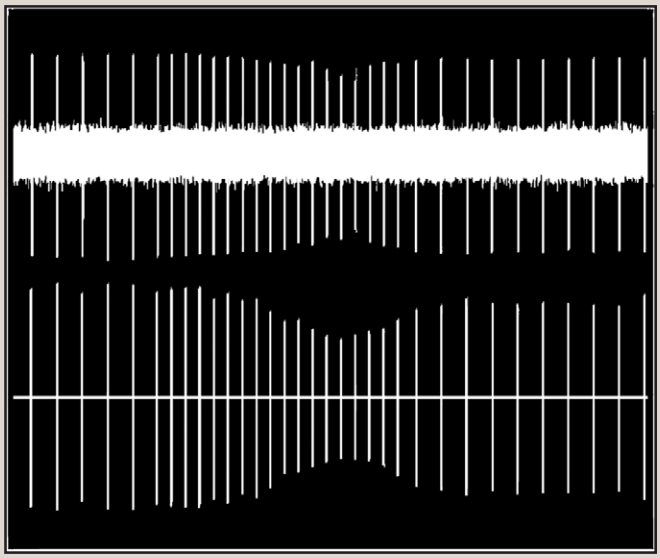

FIG. 1. Oscillograms showing a segment of an unprocessed wave file (top) and the same segment after processing for noise reduction. Vertical bars are transmitter pulses; their spacing on the time (x) axis shows the two discrete classes of pulse periods (i.e., inter-pulse interval arising from activation/deactivation of the tip-switch) whereas the differences in the bar heights show the amplitude variation.

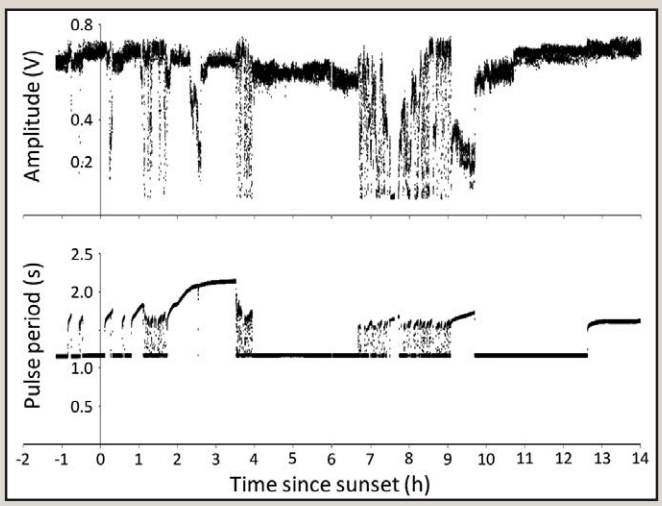

FIG. 2. Transmitter signal amplitude and pulse period variation for a fixed-station recording of a telemetered Brown Treesnake (*Boiga irregularis*) starting ca one hour before sunset and continued until ca two hours after sunrise. The transmittered snake did not move far and the antenna-receiver-recorder station was not adjusted during the recording. Notice the scatter in amplitude around 2.5 h after sunset and the lack of simultaneous scatter in pulse period (but just what appears to be a single tipping event). Such amplitude variation is often seen during rain showers. In our experience, the short-term variation in rain-caused amplitude fluctuation is normally lower than that caused by animal movements, resulting in a wavy band rather than a wide scatter.

digital recorder (Tascam DR-05; TEAC Corp., Tokyo, Japan). Because radio frequency interference was evident when the recorder was placed close to the receiver (a property of three different digital recorders we tested), we placed the receiver and recorder in different water-proof boxes that were connected by a 1-m cable. We fitted an external battery pack to the receiver as well as to the digital recorder. Recording 16-bit 44.1-kHz mono uncompressed .wav files to an 8-GB micro-SD card potentially allows for un-supervised 24-h sessions. When combined with our computer hardware, the software we used for signal analysis could not handle certain tasks if the file to be processed was too long. Instead of splitting long files, we set the recorder to limit file size to 256 MB (corresponding to a duration of ca 51 minutes), after which it started a new file.

Using low-power transmitters in a densely vegetated habitat meant that some snakes travelled sufficiently far from the station during the course of a night to cause signal loss. Snakes travelling perpendicular to the directional antenna sometimes strayed outside the detection range. Moving the station further away alleviated the latter issue but reduced the signal-to-noise ratio and increased the risk of complete signal loss due to distance. We therefore chose to visit the field site two or three times per night to see if the station had to be moved or the antenna re-directed to avoid signal loss and maintain a reasonably good signal-to-noise ratio.

A transmitter that has an average pulse rate of 0.75 s^{-1} will render 32,400 pulses during a 12-h recording session. This amount of data calls for an automated sound file analysis. We used a feature called "pulse train analysis" in the program Avisoft SAS Lab Pro (Avisoft Bioacoustics, Berlin, Germany). This feature identifies sound pulses, given user-specified detection threshold criteria, and for each pulse reports its time since the start of the analyzed time segment, the interval between the previous pulse detected and the focal pulse, the pulse amplitude (V), and its frequency (Hz). While sound pressure thresholds for detection of pulses can be adjusted in the pulse train analysis, we found that the radio frequency noise in our recordings, caused by a moderately high gain setting on the receiver, often led to a high number of false (non-transmitter) pulses detected when the signal-to-noise ratio was low. Avisoft SAS Lab Pro features a noise reduction function that removes all signals below a user-defined sound pressure threshold while retaining peaks exceeding the threshold. Using sound files from which noise has been filtered (Fig. 1) for the consecutive pulse train analysis will help generate clean data, and may under some circumstances be a good option. But when the noise reduction (or actually, the signal retention) is set to a sufficiently high precision, the file processing takes a long time even with a fast computer. (Provided that all files from a recording session have the same noise floor properties, batch processing can be used for the sake of efficacy.) When the signal-to-noise ratio is very low, relying on the noise reduction function to discard false pulses will cause transmitter pulses that are barely audible to the ear (signals with peaks that do not rise above the white noise floor) to be discarded.

We preferred to omit the processor-intensive and time-demanding noise reduction altogether. Instead, we first applied a frequency bandpass filter to help push down the noise floor relative to the transmitter signals. We then adjusted the pulse train analysis settings so that very weak and barely audible pulses were also detected. Because the transmitter pulses we recorded fluctuated in frequency with ambient temperature through a day-night-day recording session (caused by temperature dependencies in both the transmitters and the receivers, or possibly their batteries), we applied a bandpass filter that was sufficiently wide to encompass all pulses during the focal time frame. We batch-processed all files from one day-night-day session with one fixed bandpass filter, often 300 Hz wide. Depending on the circumstances, the pulse train analysis settings may be the same for all files (and files batch-processed), adjusted for each file, or

adjusted after splitting the original files into shorter files with more uniform signal-to-noise properties throughout. When the signal-to-noise ratio is low, this procedure can lead to inclusion of numerous false pulses (unless the settings are such that transmitter pulses are at risk of being discarded), and further signal discrimination is necessary.

We used IF-functions in a spreadsheet program to further discriminate signals, accepting or rejecting pulses based on their frequencies and pulse periods. The temperature-dependence of pulse frequency meant that it was not possible to use a fixed frequency range for signal discrimination. We instead created a function for a floating modal pulse frequency around the focal pulse, and then discarded pulses outside a 60 Hz frequency band centered on the current mode. In some recordings signal frequency varied considerably over short periods of time; we then used a 100 Hz pulse acceptance range. We visually inspected plots of floating modal pulses to detect outliers, often appearing when the signal was more or less lost and mostly noise was detected, and then manually inserted suitable frequency acceptance ranges for those segments. Temporal discrimination was based on the distribution of pulse periods from each recording session (as pulse period varied noticeably, not only across transmitters but also within transmitters, across nights), omitting the two tails of the bimodal distribution. Having created a spreadsheet template, we used these spreadsheet-based signal discrimination algorithms for files that had been subjected to noise reduction since they, too, included the occasional false pulse.

Our spreadsheet processing also included creation of suitable time stamps for the consecutive sound files from each recording session, as each sound file subjected to a pulse train analysis had a time stamp starting with zero. For each recording session we calculated these time stamps so that zero was the time of sunset on the focal date (Nouvellet et al. 2012), and we then plotted the pulse periods and pulse amplitudes on a timeline.

Results.—When seen in conjunction, pulse period and pulse amplitude allow a more reliable evaluation of the animal's activity patterns than does pulse period alone (Fig. 2). These activity data have high temporal resolution and can be compared with data from an on-site weather station for fine-scale evaluation of relationships between activity and environmental variables.

Discussion.—Just as non-changing pulse periods do not mean the animal cannot have moved, signal amplitude changes that suggest movement must be viewed with caution. A passing rain shower can cause noticeable fluctuations in amplitude, and this effect can linger as vegetation between the transmitter and the receiver dries out. High winds that set the intervening vegetation in motion may also cause amplitude to vary (Burger 1988), but wind should result in briefer and more back-and-forth amplitude fluctuations than do directional animal movements. With practice judging the temporal patterns of the amplitude change, such changes should be possible to tell from movements.

In our case, studying an arboreal snake that moves up and down in the vegetation, the signal amplitude changes and changes in pulse period normally agreed well (Fig. 2), suggesting that the tipping function alone would have provided sufficient data to interpret snake activity. Having access to two independent metrics nevertheless made us more confident in our interpretation of the data, especially as they were coupled with fine-grained data on precipitation and leaf wetness. We suspect that adding amplitude information may be of more benefit for those studying terrestrial animals that move over level ground or the submergence behavior of aquatic animals (Rodda 1984). Also, for those studying small animals that require lightweight transmitters, using *only* amplitude to measure activity will allow the use of regular (non-tipping) transmitters. Excluding the mercury switch will reduce transmitter weight by ca. 0.4–0.5 g and allow activity to be measured with transmitters weighing as little as 0.35 g (e.g., Holohil BD-2N).

We see both advantages and disadvantages of our method compared to the use of commercially available telemetry signal loggers, some of which register all measures we obtained from the pulse train analysis. While we have not tested such systems, we suspect that our method has the ability to render more data under poor reception conditions because we have full control over the physical signal parameters, and we can tweak noise reduction and/or pulse detection settings *after* the recording event. When several animals are transmittered simultaneously and they are located too far from each other to be monitored by one logging station, our method is also less expensive than the commercial solutions. The software we used costs ca. US $1,860 (educational price) or ca. US $2,730 (retail), and each receiving station (receiver, recorder, antenna) costs approximately US $1,000; commercially available logging stations may cost from US $4,100 (our inquiry; not including power source or antenna) to US $14,000 (Dorcas and Peterson 2012). Thus, those using the software with multiple relatively inexpensive receiving stations will achieve the best cost savings compared to purchase of multiple commercial logging stations. The major drawback with our method is that file management and analysis is very labor intensive; it can take one person a full day to complete file management, noise filtering, pulse train analyses, time stamp creation, quality control efforts, and graph plotting in a spreadsheet program for a 14-h recording session. Commercially available logging stations that provide files with pulse periods and amplitude for a full session can reduce the labor effort significantly. Since we have not tested such systems we cannot tell if that benefit outweighs the risk of more data loss when the signal-to-noise ratio is low and there is no opportunity for post-processing to optimize noise reduction and/or pulse discrimination settings to the particular signal recording.

Our method requires some practice to obtain sound files that are optimal for extraction of information. It is important to avoid use of auto level functions on the recorder, as that will eliminate any signal amplitude information. Using a limiter function is good as it prevents the recorded sound from clipping, should the animal closely approach the station, but the recording level should still be set low enough to maintain sufficient headroom to avoid amplitude information loss when the limiter kicks in. Adjusting the receiver gain, volume, and the recording level are done in conjunction; the optimal settings will depend on the hardware used, the animal's movements, and the habitat.

Bear in mind that we used small transmitters with a helical antenna spool, which had a weak signal output, and we studied mobile animals in a densely vegetated habitat. This represents a worst-case scenario, and investigators facing fewer obstacles may experience less labor-intensive field work and a simplified signal post-processing workflow. Under less challenging scenarios, simultaneous monitoring of multiple animals with recording stations similar to ours can potentially be done with even greater cost-efficacy.

Working with a Full Deck: the Use of Picture Cards in Herpetological Surveys of Timor-Leste

Timor is the 44th largest island in the world and the seventh largest between Asia and Australia (area 29,402 km^2). It occupies an extremely interesting geographical position within the biogeographical sub-region known as Wallacea, at the southeastern edge of the Lesser Sunda Archipelago and separated from Australia by the Timor Sea (ca. 450 km). This gap was considerably lessened during the final 250,000 years of the Pleistocene Epoch (2.588-0.012 MYA), when glaciation lowered sea levels by up to 120 m below present-day shorelines (Voris 2000). The Sahul Shelf of Western Australia extended to within 300 km of the Timorese coast, with stepping-stones present in the vicinity of the Ashmore and Hibernia Reefs, during at least 50% of this time and, as calculated from Voris (2000), was as close as 100–150 km for a much shorter combined period of 15,000 years.

Through the capricious nature of colonialism, Timor is politically divided into two almost equal parts. The western part (14,395 km^2: Monk et al. 1997), formerly part of the Dutch East Indies, now belongs to Indonesia's East Nusa Tenggara Province (in Bahasa: Nusa Tenggara Timur), whereas the formerly Portuguese eastern half, inclusive of the Oecusse District, an exclave surrounded by Indonesian West Timor on the northern coast of the island, and the neighboring islands of Ataúro and Jaco, comprise the 15,007 km^2 Democratic Republic of Timor-Leste (area taken from the website of the Government of Timor-Leste). The eastern part in particular has had a tumultuous and often-violent history, which has resulted in it being one of the least biologically explored islands in the region.

History of Herpetology on Timor

In terms of herpetological surveys, the port of Kupang in the western part of Timor was an important Dutch East Indian reprovisioning stop for some of the great expeditions of the early 19th century (reviewed in Kaiser et al. 2011), and a few specimens from this time exist in European museum collections (most significantly, the Muséum National d'Histoire Naturelle in Paris, France; Naturalis, formerly the Rijksmuseum van Natuurlijke Historie, in Leiden, The Netherlands; and the Zoologisch Museum Amsterdam, now also housed in Leiden). Additional short surveys were conducted there during the early 20th century (e.g., Smith 1927; collections in the Natural History Museum, London, United Kingdom) and in the 1990s (e.g., How et al. 1996a,b; collections in the Western Australian Museum, Perth, Australia). In contrast, the Portuguese eastern half of the island was not a popular shipping destination and, through the centuries, received little attention from biological, let alone herpetological, collectors. Small collections were made by Francisco Newton and co-workers (reported in Bethencourt Ferreira 1897, 1898) and during explorations for the availability of natural resources (Manaças 1956, 1972; Themido 1941). Unfortunately, all but the two specimens housed at the University of Coimbra listed by Themido (1941) were lost in the fire at the Museu Bocage, Lisbon in 1978 (Brandao 1997). Even though some collecting has occurred in Timor-Leste during the early years of independence, by batrachologist Stephen J. Richards (James Cook University, Townsville, Queensland, Australia) and ornithologist Colin J. Trainor (Charles Darwin University, Darwin, Northern Territory, Australia), no further herpetofaunal reports were available until this project was initiated in 2009.

A New Start

As a consequence of the lack of available survey data, published reports, or extant museum collections, we embarked on the first comprehensive herpetofaunal survey of Timor-Leste in 2009 working from an almost blank canvas. In our initial report (Kaiser et al. 2011), we documented the results of our first survey phase (June–July 2009), together with results from Richards and Trainor. Since then we have conducted a further six phases, at a rate of two per year, adding further species and data to our knowledge of the herpetofauna of 'mainland' Timor-Leste (O'Shea et al. 2012 and in prep.), the exclave of Oecusse (Sanchez et al. 2012), and of Ataúro Island (Kaiser et al., *in press*). The known herpetofauna currently stands at almost sixty taxa, approximately one third of them new to science.

The Need for a Tool

Part of the remit of our surveys has been to involve Timorese students from the national university (Universidade Nasional Timór Lorosa'e) in the country's capital, Dili, in the study of

MARK O'SHEA
Discovery Trail, West Midland Safari Park, Bewdley, Worcestershire DY12 1LF, United Kingdom; and School of Applied Sciences, University of Wolverhampton, Wulfruna Street, Wolverhampton, West Midlands, WV1 1LY, United Kingdom

their own herpetofauna. This process also allows these students to engage and interact with local administrators and Timorese citizens in general. The work includes promoting conservation of the Reticulated Python (*Python*[1] *reticulatus*), learning about the cultural links to the Saltwater Crocodile (*Crocodylus porosus*), and investigating the provenance of Chinese Pond Turtles (*Mauremys reevesii*) sold by the roadside in Dili (see Kaiser et al., in prep). While these types of story-telling opportunities frequently emerge when discussing nature with local residents, and while discussions of local species based on an overall '*bauplan* knowledge' of animals is quite straightforward, we wanted to ensure that we could collect local knowledge that was as detailed as possible. In this regard, researchers elsewhere noticed that the rural peoples in the Highlands language group Kalam (also known as Karam) in northeastern Papua New Guinea were able to differentiate between morphologically similar species of frogs, lizards, and snakes, and could provide separate names and even an ethnobiological classification system (Bulmer and Tyler 1968; Bulmer et al. 1975). Although a number of the frogs served as food species, several of the snakes were of 'medical importance' (see Gopalakrishnakone and Chou 1990; Jena and Sarangi 1993), and some taxa had totemic or other cultural value to local residents, many of the smaller species had no apparent bearing on the lives of the local inhabitants, yet were afforded names in the Kalam language. This level of cognitive awareness of the herpetofauna contrasts with the fact that, in many regions, harmless, inedible species are known only by a 'catch-all' common name. Bulmer and colleagues also noted that people of language groups neighboring the Kalam-speakers were less discerning and did group small reptiles together under umbrella names. The degree of local cognitive awareness relating to natural history cannot, therefore, be either simply assumed or discounted.

In an effort to maximize the exchange of information where different languages are in play, visual aids are a boon because photographs reach across the language barrier. As a consequence, we have long given thought to ways in which best to create visual aids for use during fieldwork. Although there now exist a small number of books on the herpetofauna of the Lesser Sunda Islands containing color photographs (Auliya 2007; de Lang 2011; Iskandar 1998; McKay 2006), these are not ideal as visual aids when interviewing individuals or groups of villagers, as they only permit a single open spread at any one time and often prevent the comparative examination of more than one image. The use of several books is also clumsy from a logistical viewpoint, since having to carry several guidebooks to a remote village can add considerable weight to already full packs. Some titles are also not easily or inexpensively obtained and could become spoiled by their excessive handling during fieldwork in a tropical climate. The titles listed above are also deficient in their coverage: whereas they list frogs, turtles, and snakes, they exclude lizards, which, as a group, account for approximately 66% of the reptile fauna of Timor-Leste (O'Shea et al., unpubl. data). The need for a simple, portable, visual tool, ensuring ease of use and dependability even under field conditions, was the driving force behind the idea for Species Identification Cards (SICs), which one of us (MOS) came up with in late 2011.

[1] We accept the reasoning of Zug (2011) and Kaiser et al. (2013) in retaining the Reticulated Python (*reticulatus*) and the Lesser Sunda Python (*timoriensis*) in the genus *Python*. While the data presented by Rawlings et al. (2008) indicate a split in the genus *Python*, the resulting new genus has not yet been scientifically named.

Species Identification Cards—Design

Images.—Each card displays a high resolution photograph of a reptile or amphibian, showing as much morphological detail as possible. When warranted, such as with the red flanks in sexually mature male four-fingered skinks (*Carlia* spp.) or the orange tail-tips of juvenile bent-toed geckos (*Cyrtodactylus* spp.), we included sexual or ontogenetic dichromatic variation on the same cards. With especially variable species, such as rice-paddy frogs (*Fejervarya* spp.) or Emerald Tree Skinks (*Lamprolepis* cf. *smaragdina*), the latter of which occurs as both a green-and-bronze phase or as a completely bronze phase, more than one card was produced. This approach was also taken with the Lesser Sunda Island Pitviper (*Trimeresurus insularis*); although all the specimens we have seen in Timor-Leste so far have been vivid green, one of our Timorese field colleagues assured us that the bright yellow phase, commonly seen in specimens from Wetar, an island in Indonesia's Maluku Province to the northeast, is also present in eastern Timor-Leste. For this reason a card was produced for each of the known color phases—green, yellow, and cyan—the last being the color of some Komodo Island populations. We also included species rare for Timor, those not recorded since the now lost 19th century collections of Newton were made (e.g., the Little Filesnake, *Acrochordus granulatus*, and Cantor's Watersnake, *Cantoria violacea*), as well as species reported from West Timor by earlier fieldworkers (e.g., the Crab-eating Mangrove Snake, *Fordonia leucobalia*).

How to use the Species Identification Cards
and contribute to the survey

The card set contains images of all the frogs, lizards, snakes, turtles and crocodiles currently known to live in Timor-Leste, plus extra snakes found on nearby islands, such as Flores or Sumbawa, and seasnakes & sea turtles that could occur in Timorese coastal waters. The harmless species are indicated with a green border while the dangerous species (venomous snakes and the crocodile) receive a red border and skull & crossbones icon.

Please examine all the cards and place them into three piles:
A) species you have seen near your village;
B) species you have seen in Timor but not near your village;
C) species you have never seen in Timor.

then list the card numbers on the recording sheet.

Please return the cards and the sheet to the researchers.

Thankyou.

Fig. 1. Title card (top) and instruction card (bottom) of the Species Identification Card deck used in Timor-Leste.

FIG. 2. Four sample cards from the deck of Species Identification Cards developed for Timor-Leste. Images of harmless species (top row) are framed in green, whereas images of dangerous species (bottom row) are framed in red and feature a red skull-and-crossbones symbol.

The SICs were further expanded to include all sea snakes and sea turtles likely to occur within Timorese coastal waters, and also a number of significantly important snake species from elsewhere in the neighboring Indonesian province of East Nusa Tenggara. Some of these species may yet be encountered in Timor-Leste. The reasoning behind these inclusions was that although frogs and lizards are often fairly abundant and an intensive survey will generally locate most of them, snakes are much more solitary and secretive and therefore more easily overlooked, even by experienced field herpetologists visiting an area many times over a prolonged period of time. It was primarily the desire to learn more about the snakes that initiated the SIC idea. Living and working an entire life in a localized area, the rural Timorese hunter, farmer, or fisherman is much more likely to have encountered most species inhabiting the home location than a visiting scientist. Providing a set of snake SICs is not dissimilar to showing a series of 'mug shots' or an identification line-up to a potential witness of crime. The species from outside Timor that were added to the SICs included the Lesser Sunda Catsnake (*Boiga hoeseli*) and the Common Mock Viper (*Psammodynastes pulverulentus*), both found on Flores, Alor, and Sumbawa, as well as the Indonesian Spitting Cobra (*Naja sputatrix*), found on Flores and Alor, and the Eastern Russell's Viper (*Daboia siamensis*), found on Komodo, Lembata and Flores. Also included was the Lesser Sunda Python (*Python timoriensis*), although it is now fairly certain that the type locality of Kupang, West Timor, is in error and this species does not occur on the island of Timor (see Barker and Barker 1996).

Production.—In total, a set of 99 SICs, corresponding to 51 genera and approximately 86 species (and populations that might represent undescribed taxa), was produced to standard playing card size (3.5" × 2.5" or 89 mm × 63 mm). The set of photo cards was accompanied by a title card (Fig. 1 top) and an instruction card (Fig. 1 bottom). Each SIC carries the scientific name of the species concerned (these cards also serve as teaching aids for our students) and their common names in English and, where available, in the languages Bahasa Indonesia and/or Tetun. Common names in Tetun were drawn from names that already existed in the language or, where no such names existed, from those coined by Kaiser et al. (2011), O'Shea et al. (2012), and Sanchez et al. (2012), in collaboration with Timorese colleagues. All amphibians and harmless reptiles received a green border around the photograph (Fig. 2 top), while medically important species (front-fanged venomous snakes and the crocodile) received a red border and a skull-and-crossbones icon in the bottom left corner (Fig. 2 bottom). The top left corner bears the Timor-Leste flag, the top right the project logo, and the bottom right the SIC's number. SICs were numbered sequentially by alphabetical scientific genus and species names from *Acalyptophis* to *Varanus*. This proved to be a valuable addition as it not only sped up the sorting of a used suite of SICs, it also allowed for the species to be easily listed in three columns (see below) rather than merely placed in piles. The cards were printed with the project logo reproduced on the reverse, in the style of genuine playing cards.

Six sets of cards packed in a double compartment plastic case were printed by Ad Magic, Inc. (Netcong, New Jersey, USA; www.

FIG. 3. Zito Afranio Soares (in white shirt at center left) conducting the interview in Anartutu Village on Ataúro Island.

admagic.com). One set was donated to Timor-Leste's Directorate of National Parks, while the remaining sets were distributed to the team, especially to the Timorese students.

Text.—The text of the English instruction card (Fig. 1 bottom) invites the participant by explaining "*How to use the Species Identification Cards and contribute to the survey.*" It further explains the setup of the card: "*The card set contains images of all the frogs, lizards, snakes, turtles and crocodiles currently known to live in Timor-Leste, plus extra snakes found on nearby islands, such as Flores or Sumbawa, and sea snakes & sea turtles that could occur in Timorese coastal waters. The harmless species are indicated with a green border while the dangerous species (venomous snakes and the crocodile) receive a red border and skull & crossbones icon.*" This brief summary sets the stage for the following set of instructions: "*Please examine all the cards and place them into three piles: (A) species you have seen near your village; (B) species you have seen in Timor but not near your village; (C) species you have never seen in Timor. Then list the card numbers on the recording sheet. Please return the cards and the sheet to the researchers. Thank you.*" It is our intention to reproduce additional versions of the introduction card in Bahasa Indonesia and Tetun, the *lingua franca* of Timor-Leste.

Use of the cards.—The basic premise of using SICs is straightforward: give the set to one or more individuals, who can then independently, in their leisure time, sort the cards in the manner requested. It was therefore our initial plan to leave sets of SICs in villages to which we would be returning later in a survey, asking elders and/or interested individuals to examine the cards and place them into three piles. However, our Timorese colleagues advised that it would be more productive if they conducted interviews so that they could firm up identifications with more detailed explanation if the need arose, observe the body language of those being interviewed and listen to their inflections when speaking, thereby extracting a maximum of information about the way in which the species were encountered, and also to ensure that the cards were returned afterwards. Thus, one of our Timorese team members (Zito Afranio Soares) conducted the first SIC survey amongst a group of Timorese villagers in Anartutu village (elevation 560 m), Macadade Suco, Ataúro Subdistrict, Dili District, Timor-Leste, on 29 January 2012 (Fig. 3). This was followed with an interview conducted among his workers by Barry Hinton, proprietor of the lodge Barry's Place in Beloi village (4 m elev.), Beloi Suco, Ataúro Subdistrict, Dili District, Timor-Leste, on 3 February 2012. We further used the cards opportunistically for species identification during discussions (e.g., with expatriates and Australian Army personnel we met on Ataúro Island), and we tested them informally to obtain ideas that might allow us to optimize our methodology. Although we have subsequently conducted a similar survey in a village near Balibo, Bobonaro District, on the mainland, the focus of this paper will be the two specific interviews listed above.

Results and Comments: The Numbers in the Cards

In an accounting simplified by eliminating different color variants, we report on the placement of 57 species into categories (Table 1). In nearly half of the cases (24 of 57, 42%), selections by both sets of villagers agreed with our current understanding of the Ataúro herpetofauna. Furthermore, our own collecting data supported an additional 28% of choices made in Anartutu only and 9% of choices made in Beloi only, for a total of 79% of observations with some level of agreement via the use of SICs. Whereas it is encouraging to learn that there is considerable agreement between scientists and villagers in their respective assessments, there are also signs that great care must be taken in the analysis. For example, is the reason that there is substantially higher agreement between our team and the Anartutu villagers than with the Beloi villagers (70% vs. 51%, respectively) that the people in Anartutu know their fauna better, or is the underlying reason our choice of interviewer (Timorese scientist vs. non-Timorese employer, respectively)? As with any scientific enterprise, beginnings can sometimes be perplexing, but as we gain more experience with this model of involving local residents, we anticipate being able to improve our evaluation methodology.

Results and Comments: The Anartutu Cardgame

Amphibians.—The complete absence of amphibians indicated by our interviewees was not surprising since after three surveys on Ataúro we have yet to record any amphibian species (Table 1; Kaiser et al., *in press*). However, we would have expected at least one of the villagers to have seen rice-paddy frogs (*Fejervarya* sp.) or the Common Asian Toad (*Duttaphrynus melanostictus*) on visits to Timor.

Turtles and the crocodile.—The three Timor freshwater turtles (the introduced *Mauremys reevesii* and *Pelodiscus sinensis,* and the endangered endemic *Chelodina mccordi timorensis*) were unknown to our interviewees, as were all sea turtles with the exception of *Caretta caretta* (Table 1). Curiously, *Crocodylus porosus* was also not recognized as present, even though crocodile attacks are relatively commonplace on Timor and the crocodile is part of the creation myth for mainland Timorese.

Geckos.—Whereas the house geckos *Hemidactylus frenatus, Hemidactylus* cf. *tenkatei,* and *Gehyra mutilata,* all rather similar in appearance, were considered present, the obviously flat-tailed *H. platyurus* was not (Table 1). This reflected our own experience of having collected *H. frenatus* and *G. mutilata* on Ataúro but not *H. platyurus* (Kaiser et al., *in press.*). *Gekko gecko* was listed present, as were *Cyrtodactylus* spp.

Skinks.—Almost all the cards featuring skinks (*Carlia, Eremiascincus, Sphenomorphus* spp.) were placed into Category A (Table 1). As expected, the interviewees included *Eutropis multifasciata* and both color phases of *Lamprolepis* cf. *smaragdina.* We have collected only a single specimen of the Lowland Snake-eyed Skink *Cryptoblepharus leschenault* on Ataúro, and this was the only snake-eyed skink, out of three possible species, the interviewees considered present.

TABLE 1. Results from two interviews conducted using Species Identification Cards on Ataúro Island, Timor-Leste. Responses were tallied using presence/absence categories. Cards with species known from near the interviewees' village were assigned to Category A, species known from elsewhere in Timor but not near the village to B, and species considered absent from Timor to C. In the village of Anartutu, a member of our survey team conducted the interview and all three categories (A–C) were used as intended, whereas in Beloi the interviewer lumped two categories identifying "known" species to save time. A plus sign (+) in the village columns indicates that the species was considered present, with superscripts in the Anartutu column indicating the A or B category. In the Survey Results column, a plus sign indicates that we have confirmed this species on Ataúro Island (Kaiser et al., *in press*). A minus sign (–) indicates absence. The comment section clarifies the choices made, where appropriate.

[1] Murphy et al. (2012)
[2] Barker and Barker (1996)

Agamas and Monitors.—We have failed to find any *Draco* on Ataúro and have been told previously that they do not exist there, despite the relative abundance of *D. timoriensis* on Timor. Our interviewees confirmed this by listing *Draco* as absent (Table 1). They considered the Common Tree Monitor from the mainland (*Varanus timorensis*) absent, but clearly recognized the much larger *V. salvator* complex monitor from Ataúro's coastal swamps (Table 1). While we doubt that these large lizards inhabit the area surrounding the montane village, they may on occasion be temporarily taken to the villages at higher elevation to function as a totem in conflict resolution (see Kaiser et al., in prep).

Marine snakes.—Sea snakes and sea kraits were included among the SICs with the expectation that they would primarily be identified by residents of coastal villages. However, our mountain village interviewees identified *Acalyptophis, Enhydrina,* and *Astrotia* as seen nearby (Table 1). All other taxa, *Hydrophis, Lapemis, Laticauda,* and *Pelamis,* were unrecognized. Since *Enhydrina* inhabit turbid estuarine environments and *Astrotia* is a rarely encountered, open-water species, these are likely to be errors that stem from a relative unfamiliarity with the species.

Terrestrial snakes.—The interviewees recognized the same species we have recorded from Ataúro (*Coelognathus subradiatus, Lycodon capucinus, Ramphotyphlops* sp.; Table 1). They also included the green and cyan color phases of *Trimeresurus insularis* but not the yellow phase found on neighboring Wetar. One python species, *Liasis mackloti*, was recognized, but neither *Python reticulatus* nor *P. timoriensis* were considered present.

Among the other recognized species were *Cylindrophis boulengeri* and *Brachyorrhus albus*. Whereas the former is known from eight specimens collected on Timor (Forcart 1953), records for the latter from Timor appear to have been in error (Murphy et al. 2012). The bronzeback *Dendrelaphis inornatus timorensis*, which we sighted but failed to capture, the catsnake *Boiga hoeseli*, a species not known from Timor but recorded from Alor, Ataúro's western neighbor, and *Stegonotus*, a genus not recorded from Timor until 2011, were also considered to be present (Table 1).

As seen in Timor but not near the village (Category B), our interviewees selected *Acrochordus granulatus, Cantoria violacea,* and *Fordonia leucobalia*, all mangrove swamp species (Table 1). Aside from a few very small mangrove lagoons along its northeastern shore, Ataúro has no suitable mangrove swamps for these species, but such habitats exist near Dili on the mainland. A fourth and seemingly more common taxon from the same habitat type and also rice-paddy, *Cerberus rynchops*, was not selected.

A worrying inclusion in the "seen but not nearby" category was the highly venomous *Daboia siamensis*, probably the most dangerous snake in the Lesser Sunda Archipelago, which is not known to occur as far east as Timor. However, the occurrence of *Daboia* has been verified from Lembata, an Inner Banda Arc neighbor of Ataúro, three islands removed. Therefore, it is possible that the interviewees did not remember that our question restricted their observations to Timor and that their familiarity extends to a species from a nearby island. Were this species present on Timor, we would have expected to reveal a medical history of serious snakebites, including fatalities.

Apart from the species mentioned above, the rarer wolfsnake *Lycodon subcinctus*, the mock viper *Psammodynastes pulverulentus*, known from Alor and other islands to the east but not Timor, and the spitting cobra, *Naja sputatrix* were also not selected (Table 1). Non-recognition of *N. sputatrix* by people from the higher elevations on Ataúro does not contradict anecdotal evidence we have collected regarding its presence on the island, because spitting cobras are lowland habitat generalists.

Conclusions of the Anartutu interview.—Our interviewees' observations coincided very closely with our own field experience, especially with regards to amphibians, turtles, the crocodile, and lizards, with the possible exception of the inclusion of *Carlia* as present on Ataúro. The exclusion of *Draco timoriensis* and *Varanus timorensis*, but the inclusion of the large *Varanus* was especially in agreement with our own findings. Even among the more elusive and generally feared snakes there was a great deal of agreement between the interviewees and our data, with all the species we had recorded being recognized (Table 1). The inclusion of several seasnakes and *Daboia* were unexpected, as was the exclusion of *Naja* and *Python reticulatus,* whereas the inclusion of *Cylindrophis*, *Brachyorrhus, Boiga,* and *Stegonotus* suggests more fieldwork is required on this rugged island.

Results and Comments: The Beloi Cardgame

The Anartutu village survey can be compared with a similar survey conducted with workers at Barry's Place, an eco-resort on the coast just north of Beloi village, who are more likely to be widely travelled and familiar with species from the mainland. In this survey the interviewer (the employer Barry, a Tetun-speaking Australian) simplified the trial on his own initiative during the interview by combining both categories indicating familiarity (Categories A and B), presumably to encompass Ataúro in a single category.

Amphibians.—The eco-resort workers recognized *Duttaphrynus, Fejervarya,* and *Polypedates* but excluded the three localized mainland amphibians (*Kaloula* cf. *baleata, Limnonectes timorensis, Litoria everetti*; Table 1).

Turtles and the crocodile.—Again *Crocodylus* and the three freshwater turtles were unfamiliar, but sea turtles were sorted in an exact contrast to the previous interview: *Dermochelys, Chelonia,* and *Eretmochelys* were included, *Caretta* was excluded (Table 1).

Geckos.—As in the previous interview, *Cyrtodactylus, Hemidactylus, Gehyra,* and *Gekko* were familiar (Table 1), although a striped *H. frenatus* was omitted. However, the workers also recognized *H. platyurus*, a species we do not yet know from Ataúro.

Skinks.—Every single skink was recognized (*Carlia, Cryptoblepharus, Eremiascincus, Eutropis, Lamprolepis, Sphenomorphus*). The inclusion of the endemic mainland *Cryptoblepharus* spp. was obviously an error but the inclusion, once again, of the unverified *Carlia* was interesting.

Agamas and monitors.—*Draco* was again unrecognized, but *Varanus timorensis* was included, possibly being mistaken for juveniles of the familiar, larger Ataúro swamp monitor (Table 1).

Marine snakes.—Curiously, all the species pictured were listed as present (Table 1) but it is possible the workers included some former net fishermen used to removing seasnakes from their nets and seeing a flattened tail assumed they were all the same.

Terrestrial snakes.—The workers agreed with both ourselves and the previous interviewees by including *Coelognathus subradiatus, Trimeresurus insularis* (with all three color phases), *Lycodon capucinus,* and *Ramphotyphlops* spp., while excluding *Lycodon subcinctus* (Table 1). They agreed with the first interviewees and our suspicions by including *Dendrelaphis inornatus* and *Boiga hoeseli,* but they erred in including *Brachyorrhus* and *Stegonotus.*

Unlike the Anartutu interviewees, the workers included *Acrochordus, Cerberus, Fordonia,* and *Naja* as present but excluded *Cylindrophis, Cantoria, Liasis,* and *Daboia.* They also included *Python timoriensis* but excluded *P. reticulatus.* If *P. timoriensis* is to be found anywhere in Timor-Leste, then Ataúro, being close to its easternmost record of Alor, is the most likely location.

Conclusions of the Beloi interview.—Among the obvious differences in how this interview was conducted is that the person doing the interview was not a native Timorese and that two categories were lumped together. While it may be easy for an employer inspired by a herpetological survey to gather employees for this type of exercise, we are not certain how effectively someone largely unfamiliar with the featured species can conduct the interview. It also occurred to us that employees might try to please their employer by answering in the positive more frequently than warranted. Overall, we again found considerable overlap with our own collections, even though there were some discrepancies such as the inclusion of mainland species as present on Ataúro. It is interesting that our survey has not revealed a single species on Ataúro not already known, and therefore selected, by at least one of the interviewees.

Discussion

Based on our specific test interviews, we find that the use of SICs alongside traditional survey methods shows great promise. Having used SICs in situations where we had some prior knowledge of the existing fauna allowed a reasonably good assessment of how to optimize use of SICs. Furthermore, we were also in a position to determine whether the results could add useful information to our survey efforts. Having completed these initial trials, we recognize the benefits of SICs, but we freely admit that there is room for improvement.

Interview optimization.—Based on the two interviews presented here in detail, as well as on several others conducted in mainland Timor-Leste, there are several ways by which use of SICs and the associated interviews can be improved. Firstly, our Timorese colleagues suggested that it would work best if we, as *malaes* (Tetun: foreigners) kept our distance, because they believed that during an interview villagers open up more to a fellow Timorese when foreigners are absent. The Anartutu interview was conducted in this way, whereas the eco-resort interview was conducted by the workers' Australian employer, a resident but nonetheless a *malae*. This may have led to differences in the interpretation of what was required of both the interviewers and the interviewees, and an increased desire to please by answering in the affirmative. In general, the interview ought to garner the best results if it is conducted by a team member indigenous to the survey area and not by actual or perceived outsiders.

Secondly, for the interview process it is essential that the interviewer have intimate knowledge of the animals surveyed as well as their habits and habitats. This is essential for the interviewee(s) if questions about the card arise, and it is important for the interviewer to ascertain whether positive identifications reflect the reality of a habitat and the probability of the encounter actually having taken place; refining questions can then be asked by the interviewer to eliminate doubts.

Thirdly, while it is certainly possible that interviews of multiple interviewees provide more results (i.e., animals recorded) more quickly, this may create a distracting group dynamic. For example, if one individual in a group is found not to be able to answer the interviewer's request for clarification, this may cause embarrassment and subsequent reluctance on the part of the interviewee to answer further questions (or to speak up at all), and on the part of the interviewer to ask that particular interviewee for further clarification questions in order to avoid further

embarrassment. We would consider individual interviews optimal, although we realize that in the village dynamic this may have to be an area for compromise since the deliberate exclusion of villagers wanting to participate may lead to resentment and future difficulties with fieldwork in the area.

Card optimization.—From a visual perspective, we found the design of the cards to be appropriate and effective overall. In order to provide size information, we had added a scale in the shape of a snake with expected ranges in length to the images of *Ramphotyphlops braminus* and *R. polygrammicus*, since these snakes are fairly uniform in body shape and coloration and difficult to differentiate for non-experts in the absence of size. This may be a useful addition to these cards in general. We also determined that some refinements were needed in the text. For example, the parameters of what constitutes a category need to be more finitely determined. Using Category B on Ataúro in its current incarnation, it could be seen as applying to "elsewhere on Ataúro" or even as "elsewhere on neighboring islands," when it was intended to indicate "elsewhere in Timor-Leste." Furthermore, the addition of cards in Bahasa Indonesia, Tetun, and possibly other local languages might be important so that both the indigenous interviewer and the interviewee(s) are able to refer to it frequently as decisions about card placement are made.

A final thought.—A possible follow-on worth considering for SICs, once a survey is complete and most, if not all, amphibians and reptiles have been documented, is to produce suits of cards as genuine playing cards, allowing both adults and children to use them as a popular form of wildlife and conservation education through entertainment.

Acknowledgments.—Our research in Timor-Leste has greatly benefited from the personal attention of Xanana Gusmão, the Prime Minister, and of José Ramos-Horta, the country's President in office at the time of our visits. We sincerely thank Their Excellencies for this level of support. We could not have carried out our surveys without the efforts of Claudia Abate-Debat, Senior Advisor to the Prime Minister, whose many intercessions on our behalf smoothed out the wrinkles research can throw one's way. Our gratitude for the issuance of research and export permits goes to Manuel Mendes, Director of National Parks. Special thanks to Ruud de Lang, who kindly provided several images of species for which we lacked photographs. We thank our interviewers, Zito Afranio Soares and Barry Hinton, as well as our team of field assistants, including Agivedo Varela Ribeiro, Zachary Brown, Melissa Carrillo, Scott Heacox, Stephanie Hughes, Aaren Marsh, Gloria Morales, Justin Rader, Caitlin Sanchez, and David Taylor. Financial assistance in support of student travel was provided by the Associated Student Body at Victor Valley College and through donations to the Victor Valley College Foundation. This is contribution No. 10 from the Tropical Research Initiative at Victor Valley College.

A Comparison of Two Methods to Assess Territorial Aggression in the Lizard *Uta stansburiana*

Techniques to assess social behavior, and especially territorial aggression, are as diverse as the behaviors they measure. Aggression has been measured in response to many types of stimuli: conspecific tethered intruders, mirror images, video-playbacks, and even robotic models. These stimuli may be interpreted differently by males and females, individuals with differing social status or condition,different aged individuals, etc., and these groups of individuals may respond in disparate ways. Also, it is important to note that the methods commonly used in the laboratory may not yield comparable results in the field. We used two methods to assess territorial aggression in the lizard *Uta stansburiana*. Due to strong sexual differences in morphology and behavior and the known costs of tail autotomy on social status in *U. stansburiana*, we felt it would make an excellent organism to compare and contrast two field methods, and at the same time evaluate how autotomy impacts territorial aggression. Lizards, especially small territorial ones like *U. stansburiana*, are excellent models to study social behavior (Fox 1983; Fox et al. 2003). They are often abundant, easily captured, individually identifiable, and exhibit stereotypical complex behavior—all traits that make them ideal subjects for studies of social behavior. Lizard territoriality especially has been thoroughly studied (Fox 1983; Fox et al. 2003; Stamps 1977). In lizards, field studies often rely on two methodsto quantify territorial behavior of residents: unmanipulated, time-constrained, focal observations (Baird et al. 1996; Baird et al. 2001) and experimental placement of tethered intruders into a resident's territory (Fox and Baird 1992; Husak et al. 2006; Moore 1987; Stamps 1977, 1978). Studies of dominance and territoriality in the laboratory use a different set of techniques, including dyadic contests in neutral arenas (Fox 1983; Fox et al. 1990; Husak et al. 2006; Karsten et al. 2009), mirror stimuli (Brandt 2003; Brandt and Allen 2004; Hurd 2004; Korzan et al. 2000; Watt et al. 2007), and video playbacks (Clark et al. 1997; Macedonia 1994; Ord et al. 2002). Mirrors work in laboratory settings to induce aggressive responses in lizards as well as in fish, birds, and primates (Bisazza and de Santi 2003; Gallup Jr. 1968; 1970; Gouchie et al 2008; Hirschenhauser et al. 2008; Moretz et al. 2007). The intensity and duration of lizard responses in the laboratory to a mirror have been used to measure endurance and aggression in lizards (Brandt 2003; Brandt and Allen 2004; Watt et al. 2007). However, the use of a mirror to induce an aggressive response from territorial lizards in nature has not previously been attempted. We took the mirror technique and transported it to the field to quantify territorial aggression. The tethered intruder method is a standard way to assess territoriality in the field. We compared the field-based standard of tethered intruder method to the typically laboratory-used mirror image intruder method, but here employed in the field.

We used the lizard *Uta stansburiana* for these tests because it is an abundant, territorial lizard with clear sexual differences in morphology and behavior and is easily observed with minimal disturbance. *Uta stansburiana* at our study site experiences frequent tail autotomy (Fox and McCoy 2000; Tinkle 1967),and in this population the tail is used by subadults as a social signal (Fox and Rostker 1982; Fox et al. 1990). The benefit of tail autotomy is escape from predation; however, numerous costs are incurred post-autotomy, including decreases in performance, loss of caudal resources, and altered social and territorial behavior (reviewed in Arnold 1984 and Bateman and Fleming 2010). Therefore we also examined the impact of autotomy on territorial behavior.

The objectives of this study were to 1) compare the intensity and types of aggressive displays in the field against a mirror-reflected intruder versus a real, tethered intruder, and 2) evaluate differences in aggressive response due to sex and tail condition.

Materials and Methods

The study was conducted at a site in Winkler Co., Texas, USA, located on a large cattle ranch and oil/natural gas field, from early March to late May 2009, the breeding season of *U. stansburiana* in western Texas. This site has been used for numerous studies examining the demography, life history, and behavioral ecology of *U. stansburiana* over the last 50 years (Anderson et al. 2012; Fox 1978; Fox and McCoy 2000; Tinkle 1962, 1967).

Method 1: Tethered Intruder.—This method requires a size- and sex-matched intruder to be introduced into the territory of a resident lizard (Stamps 1977, 1978). Some residents had fully intact tails while others had autotomized tails in various stages of regeneration. For intruders, we used lizards collected from an offsite area of similar habitat. All intruders had fully intact tails. The intruders were kept in the laboratory in individual plastic cages and taken to the field only on the day of their trials. Intruders were provided with mealworms (*Tenebrio* sp.) *ad libitum* and their cage walls were misted with water each day. Intruders exhibited no signs of deterioration in condition due to captivity or manipulation, and were replaced with a new offsite lizard after several trials. Each intruder was paint marked with a single

dorsal stripe (blue or red). Intruders were sorted into three categories: small, medium, and large (males: 42–45, 46–49, and 50–52 mm SVL, respectively; and females: 39–42, 43–46, and 47–50 mm SVL, respectively). Intruders were the same sex as the resident and matched in size as closely as possible. Each intruder was used at most twice a day, with the two trials separated by at least 4 hours. The intruder was secured (tethered) to a 3-m telescopic pole via a 10-cm segment of monofilament fishing line around its waist. Intruders were placed approximately 1 m from a targeted resident. The intruder's presence and/or behavior usually elicited a response from the resident;however, since the intruder was tethered, it could not chase the resident and never attacked it.

All trials were conducted by one investigator (LAW) and all behavior performed during a 10-minute trial was recorded. *Uta stansburiana* has very stereotypical territorial behavior, consisting mainly of headbobs, pushups, lateral displays, and circling, which have been observed and catalogued with relation to aggression in previous studies (see Table 1 modified from Fox 1983). Sometimes, aggression can escalate into a fight, with chasing and biting occurring. At this site, *U. stansburiana* seems largely unaffected by the presence of humans, often foraging or interacting with conspecifics within just a few feet of the observer. Trials were carried out during the morning (0900–1300 h) and then again in the late afternoon (1600–1930 h), corresponding with peak activity of *U. stansburiana*at the study site (Irwin 1965; Tinkle 1967; Anderson, pers. obs.). Weather conditions were similar for all trials and an effort was made to avoid excessively hot or windy conditions.

Table 1. Behavior patterns recorded and point values used to score total (raw) and weighted aggression.

Behavior Score	Type (aggressive or submissive)	Score	Weighted
Attack	Aggressive—resident runs toward and tussles with intruder	+1	3
Bite	Aggressive—resident bites intruder	+1	3
Superimposition	Aggressive—resident sets limb or body over intruder	+1	3
Lateral Display	Aggressive—resident extends limbs to raise the trunk of the body above the ground, while dorsoventrally compressing the torso and inflating the dewlap	+1	2
Pushup	Aggressive—resident performs rapid up and down movement in which the trunk of the body is raised off of the ground	+1	2
Lick	Aggressive—resident licks intruder	+1	2
Circling	Aggressive—resident moves in a semi-circle or circle around intruder, often while performing other aggressive acts	+1	2
Headbob	Aggressive—resident performs up and down head movement without raising the trunk	+1	1
Approach	Aggressive—resident moves toward intruder	+1	1
Flee	Submissive—resident quickly and deliberately retreats from intruder	-1	-1
Flatten	Submissive—resident presses trunk of body and limbs flat against the ground	-1	-1

Table 2. Size (SVL) comparison between resident lizards challenged with a real, tethered intruder or the mirror-image intruder (t-tests).

Sex	Intruder Type	Sample Size	SVL (mm) ± 1 SD	t-statistic	df	P-value
Male	Mirror	12	50.83 ± 3.5	0.568	30	0.574
	Tethered	20	50.20 ± 2.29			
Female	Mirror	22	46.50 ± 1.82	1.184	48	0.242
	Tethered	28	44.21 ± 8.89			

Method 2: Mirror-Image Intruder.—We custom designed a mirror for field use. The device consisted of a flat mirror (61 × 30.5 cm) mounted to a plywood board of similar dimensions. This board was connected to a 2–4 m collapsible pole. The pole was made of aluminum and lightweight, but rigid enough to support the weight of the mirror and board. This device was carried into the field and deployed once a resident lizard was located (Fig. 1). A different subset of resident lizards was used from those in Method 1.The mirror image was always size-, sex-, and condition- matched (including tail status) to the resident. The behavior of the intruder was also identical to the resident. So if the resident escalated its aggression, so did the intruder, and this cycle continued throughout the trial.

To deploy the mirror, the collapsible pole was extended to an appropriate length and the mirror was placed on the ground directly in the resident's line of sight. Due to the loose, sandy soil at the study site and the weight of the mirror/board, the mirror was easily placed at ground (lizard eye) level. If during this process the lizard fled from the experimenter, the trial was aborted and tried again later (> 5 h).

Once the mirror was in place the trial began. All trials were observed by one investigator (LAW), and all behavior performed during the trial was recorded. Mirror trials were carried out during the morning (0900–1300 h) and late afternoon (1600–1930 h). Weather was similar for all trials, and again an effort was made to avoid excessively hot or windy conditions. Duration of the trials was dependent on the resident lizard. We tried to conduct 15-min trials, but in many cases had to cut the trial short because the intruder lost sight of the mirror image and left the area.

To account for the varying and different durations of the two methods, all frequencies of behavior patterns were converted to a common 10-min basis. Three dependent variables were calculated for each trial: total (raw) aggression, weighted aggression, and trial aggression. Total (raw) aggression is the sum of all agonistic behavior patterns observed during a trial; behavior patterns were categorically assigned a +1 if aggressive, and a -1 if submissive. The weighted aggression score is the sum of all agonistic behavior patterns observed during a trial, but each behavior pattern is given a weight from +3 to -1, based on the intensity of the behavior. See Table 1 for a detailed description, categorization of aggressive or submissive, and weights for each behavior pattern. Trial aggression was a single value based on the sequence of aggression observed during the trial; each trial was scored from zero to 5 (0 = immediately flee, 1 = no response, 2 = display then flee, 3 = display with no subsequent fight or flee, 4 = display then fight, and 5 = fight then display). Total Aggression and Weighted Aggression werelog transformed to ensure normality,and in all cases in which parametric statistical tests were used, distributions of transformed data were normal (Kolmogorov-Smirnov tests, all $P > 0.05$). Non-parametric tests were used in the case of Trial Aggression since this was an ordinal, and not continuous, variable. All statistical comparisons were made using the statistical package SPSS (IBM Corp. Ver. 19.0).

Results

During the spring of 2009, 48 tethered intruder and 33 mirror intruder trials were completed. Tethered intruders were introduced into the known territories of 20 male and 28 female lizards. The mirror was tested in the territories of 11 males and 22 females. Fewer males were tested because this population of *U. stansburiana* is female-biased, potentially due to differential predation pressure on the males. Males are more conspicuously colored, larger bodied, and defend larger territories, all of which may contribute to higher death rates due to predation(Constantini et al. 2007; Husak et al. 2006; Magnhagen 1991; Stuart-Fox et al. 2003). Size of the resident can affect aggressive response, but there was no significant difference in size of either male or female residents tested with the tethered intruder versus the mirror image (all $p > 0.05$; see Table 2 for details of morphological comparisons).

We first determined that *U. stansburiana* would act aggressively toward a mirror-image intruder in a natural setting. We observed an aggressive response from residents in 22 of 33 trials (67%). Of the 11 trials without aggression, in onethe resident fled from the mirror and in 10 the resident showed no response. Comparing this to the introduction of real, tethered intruders, 29 intruders in 48 trials (60%) elicited aggression. We conclude that the mirror image of an individual *U. stansburiana* can elicit aggressive behavior from free-living, territorial resident lizards.

Within method analysis: Tethered Intruders.—Using a full-factorial two-way ANOVA, the interaction between the effects of sex and tail status on Total Aggressive response to a tethered intruder was non-significant ($F_{1,47} = 0.0010$, $P = 0.971$). Considering main effects, males were significantly more aggressive toward a tethered intruder than females ($F_{1,47} = 6.833$, $P = 0.013$; Fig. 2a), but there was no significant difference between tail status groups ($F_{1,47} = 0.970$, $P = 0.758$).When examining Weighted Aggression toward a tethered intruder, we found no significant interaction between sex and tail status ($F_{1,37} = 0.001$, $P = 0.992$). Considering main effects, males were significantly more aggressive toward a tethered intruder than females ($F_{1,37} = 7.102$, $P = 0.012$; Fig. 2b) and there was no significant difference between tail status groups ($F_{1,37} = 0.058$, $P = 0.812$). Trial Aggression was assessed using the Mann-Whitney U Test. Males responded more aggressively against a tethered intruder than females (Mann-Whitney $U = 109.0$, $n_1 = 20$ $n_2 = 27$, $P < 0.0001$ two tailed; Fig. 2c). Tail status did not affect Trial Aggression for males (Mann–Whitney $U = 46$, $n_1 = n_2 = 10$, $P = 0.745$ two-tailed), or for females (Mann–Whitney $U = 60.0$, $n_1 = 11$ $n_2 = 16$, $P = 0.144$ two-tailed).

Fig. 1. The custom-designed mirror on a pole used to elicit territorial aggression. The pole is telescopic (2–4 m) and made of lightweight aluminum.

Within method analysis: Mirror Image Intruders.—No significant interaction between the effects of sex and tail status on Total Aggression toward a mirror image intruder was detected ($F_{1,22} = 0.008$, $P = 0.929$). Analysis of simple main effects showed that males were not more aggressive toward a mirror image intruder than females ($F_{1,22} = 1.074$, $P = 0.142$) and there was no significant difference between responses with respect to tail status ($F_{1,22} = 0.159$, $P = 0.564$). No significant interaction effect was detected between the effects of sex and tail status on Weighted Aggressive response to a mirror image intruder ($F_{1,26} = 0.032$, $P = 0.860$). Males tended to be more aggressive than females; however, this difference was not statistically significant ($F_{1,26} = 2.738$, $P = 0.111$). There was no significant difference with respect to tail status ($F_{1,24} = 0.301$, $P = 0.589$).Trial Aggression within mirror image intruder trials was assessed using the Mann-Whitney U Test. Trial Aggression was the same between male and female residents (Mann-Whitney $U = 97.0$, $n_1 = 11$ $n_2 = 22$, $P = 0.300$). Tail status did not affect Trial Aggression for males (Mann-Whitney $U = 14.5$, $n_1 = 6$ $n_2 = 5$, $P = 0.892$ two-tailed), nor females (Mann-Whitney $U = 46.0$, $n_1 = 12$ $n_2 = 10$, $P = 0.319$ two-tailed).

Between methods analysis.—To compare the two methods, we separated the sexes due to the sexual differences detected in the within method analysis. However, tail status was removed from the analysis; lizards with recent tail autotomy and those with intact tails were pooled.

Males responded to the two methods with significantly different amounts of Total Aggression ($F_{1,31} = 4.169$, $P = 0.050$; Fig. 3a). They responded with almost 1.5 times the mean aggressive behavior per 10-minute trial toward the tethered intruder than the mirror image intruder. Weighted Aggression from males toward the two types of intruders showed a similar tendency, but it was not statistically significant ($F_{1,31} = 3.681$, $P = 0.065$; Fig. 3b). Females did not show a difference in response to the two

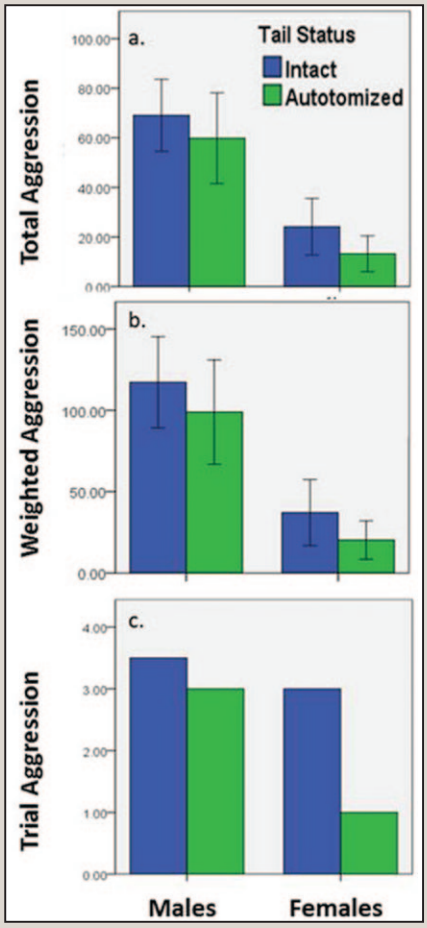

FIG. 2. a) Total Aggression directed at a tethered intruder was significantly different for the sexes ($F_{1,47}$= 6.833, P = 0.013), but both sexes responded similarly regardless of tail status ($F_{1,47}$ = 0.0010, P =0.971). Error bars represent ±1 SE. b) Weighted Aggression directed at a tethered intruder was significantly different for the sexes ($F_{1,37}$ = 7.102, P =0.012), but both sexes responded similarly regardless of tail status ($F_{1,37}$ = 0.001, P =0.992). Error bars represent ±1 SE. c) Males responded with greater Trial Aggression than females when confronted with a tethered intruder (U =109.0, P <0.001), butboth sexes responded similarly regardless of tail status.

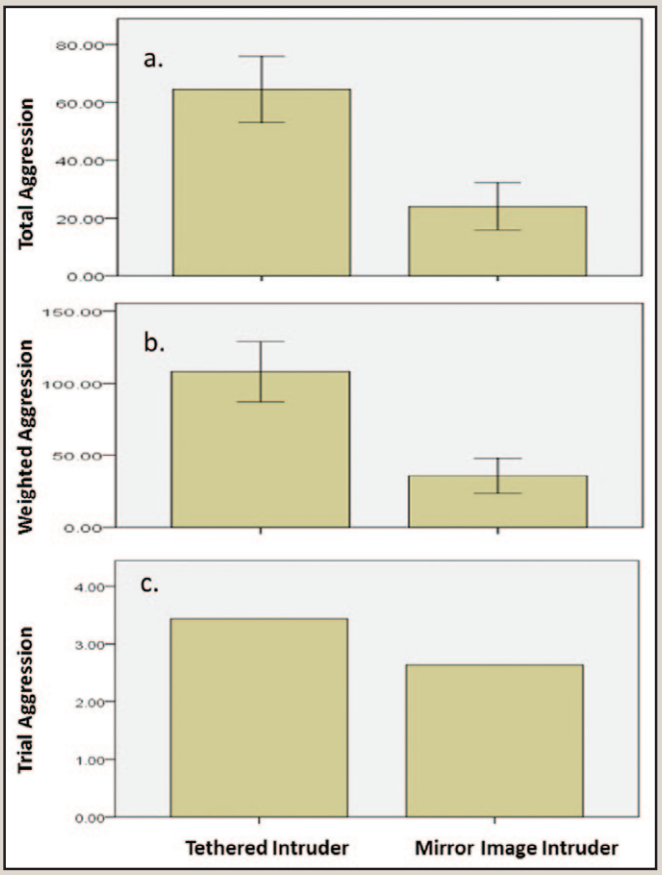

FIG. 3. a) Total Aggression displayed by males in response to the two methods (tail status of males pooled). Males responded to the tethered intruder with significantly more Total Aggression than they did towards a mirror image intruder ($F_{1,31}$ = 4.169, P =0.050).Error bars represent ±1 SE. b) Weighted Aggression displayed by males in response to the two methods (tail status of males pooled). Males responded to the tethered intruder with marginally more Weighted Aggression than they did towards a mirror image intruder ($F_{1,31}$ = 3.681, P =0.065). Error bars represent ±1 SE. c) Trial Aggression displayed by males in response to the two methods (tail status of males pooled). Male responses to the tethered intruder weregreater than their responses to a mirror image intruder (U = 60.5, P = 0.022).

responded with equal Total Aggression regardless of intruder type ($F_{1,32}$= 1.070, P = 0.309). Because variances of weighted aggression between the two methods were significantly non-homogenous for females, we used the nonparametric Mann-Whitney U-test to detect differences in Weighted Aggression to tethered intruders and mirror image intruders. The response of females was not significantly different (Mann-Whitney U = 270.0, n_1 = 27, n_{22} = 22, P = 0.580). Trial Aggression between tethered intruder and mirror image intruders was assessed by the Mann-Whitney U Test (tail status groups pooled). Trial Aggression of males against tethered and mirror intruders was significantly different (Mann-Whitney U = 60.5, n_1 = 20 n_2 = 11, P = 0.022 two-tailed; Fig. 3c). Trial Aggression of females was not different (Mann-Whitney U = 236.5, n_1 = 27 n_2 = 22, P = 0.198 two-tailed).

Additionally, we observed that residents (males more than females) presented with a real, tethered intruder not only scored higher quantitatively on indices of aggression, but they also behaved differently in a qualitative sense. Real intruders were attacked and ultimately bitten more. In 380 minutes of tethered intruder trials, 39 attacks and 27 bites were recorded, compared to only 5 attacks and no bites in 412 minutes of mirror trials. A major component of the stereotypical territorial encounter in *U. stansburiana* is a phase of circling the intruder. In doing so, the resident dorsoventrally compresses its body, inflates its dewlap, and struts around the intruder in a tight circle. This behavior is a sign of escalating aggression and typically leads into a rough-and-tumble fight. During the 380 minutes of tethered intrusions, 31 instances of circling were recorded, as opposed to only 2 instances in 412 minutes of mirror intrusions.

DISCUSSION

The mirror successfully elicited territorial aggression in 67% of the trials. This was similar to the rate (60%) of eliciting territorial aggression toward a real, tethered intruder (χ^2 = 0.328, df = 1, P = 0.567). However, the intensity and duration of the aggression against a tethered individual was noticeably different, especially in males. Residents attacked, and ultimately bit, real, tethered intruders more often than they tried to attack the mirror. The residents also used their full repertoire of territorial

behavior against tethered intruders, including circling and lateral compression displays. These behavior patterns were much less frequently used against a mirror intruder. With the mirror technique, a resident cannot really circle the intruder, nor bite the plane of the mirror. In general, males responded significantly more aggressively than females toward a real, tethered intruder, but this sexual difference was not observed against a mirror image intruder.

Previous laboratory studies have shown decreases in social status for juvenile *U. stansburiana* during neutral arena dyadic encounters following tail autotomy (Fox and Rostker 1982; Fox et al. 1990). We did not detect lower aggression from resident lizards with recent tail loss for any of the measures used in this field study. However, our methods differed significantly from those in the earlier studies, and the sudden appearance of an intruder (whether tethered or mirrored) into the territory of a resident may be impossible for tailless individuals to ignore. Our methods did not assess whether the resident would have won the encounter with the intruder, just its overall response. Perhaps the cost of territorial incursions by intruders is so high that residents must respond, regardless of tail status. Repeating laboratory dyadic encounters with adult lizards with and without tail loss is worth further investigation.

The use and limitations of tethered intruders to assess territoriality in the field have been discussed elsewhere (Civantos 2000; Fox and Baird 1992; Husak 2004; Husak and Fox 2003), so we focus instead on our novel use of the mirror intruder method deployed to assess territorial aggression in the field. Even though the mirror method did not elicit as high a level of aggression nor all the aggressive behavior patterns as the real, tethered intruder, this method does have some obvious benefits. The mirror projects an image of the intruder that is exactly matched to the resident with respect to size, sex, and condition. This is a major advantage because with the use of real, tethered intruders, care must be taken to ensure an appropriate match between resident and intruder, which is never perfect. Additionally, small subsets of intruders are used often, which can sometimes lead to deterioration in condition or motivation of the intruder and ultimately decreased aggression from the resident. The mirror image always "responds" in kind to the resident's behavior. This is not the case with a tethered intruder, who may or may not respond to the resident. This mirror response might show display endurance (Brandt 2003; Brandt and Allen 2004) and willingness or ability to escalate aggression (Cox et al. 2009) more reliably than a real intruder since the mirror image always responds aggressively to an aggressive resident.

In some studies the use of tethered intruders might not be practical or ethical. In cases where lizards are especially large (e.g., large iguanids or varanids) the tethering of an intruder seems impractical at best and might be dangerous to both investigator and the lizard. For threatened, uncommon, or endangered species, there may be legal or ethical concerns with tethering an intruder into the territory of a resident. Tethering, if done correctly, is a standard and safe method and does not cause long-term harm to the intruder. However, it might cause temporary stress to the tethered intruder because the intruder cannot flee and avoid the aggression of the resident, but it is unknown if this temporary stress is more than an unmanipulated, natural intruder experiences. In these cases, use of the mirror technique in the field might be a more suitable alternative.

The use of the mirror in a field setting does present some limitations. The most obvious limitation is the logistic demand of carrying a large, cumbersome mirror-on-a-pole into the field. The entire device weighed almost 4.5 kg, even with the modifications we made. For the pole, we used a lightweight aluminum pole used in swimming pool maintenance, and we constructed the backing board out of thin plywood. The placement of the mirror at our desert study site was made relatively easy due to the sparse vegetation and the sandy soil. Our method might not work in densely vegetated habitats or in rocky soils.

Another major limitation is lack of control of the stimulus of the mirror intruder. Basically, the resident loses focus on the intruder when the intruder passes out of sight. Unlike the tethered intruder technique (where the intruder is anchored to one small area), the mirror image may disappear during the trial when the resident moves too much to the side of the mirror. We observed this phenomenon, and we also sometimes witnessed the resident reach the edge of the mirror, lose the intruder, turn and walk back in front of the mirror. At this point the intruder "returns," and the resident begins its aggressive behavior again. To minimize this shortcoming, the size of the mirror must be appropriate for the size of the lizards. At our study site, adult *U. stansburiana* are approximately 48 mm in SVL, and the mirror was 610 mm in length, almost twelve times the lizard's body length. This size of the mirror allowed the resident ample opportunity to move while displaying, and never lose sight of the mirror image. For larger-bodied lizards, a larger mirror would be needed, but makes the device even heavier and more cumbersome.

The last limitation of the field mirror technique is that the deployment of the mirror can spook the resident lizard and cause it to flee. This occurred in a number of early trials, but, as with all techniques, with practice the investigator (LAW) became much more proficient at placing the mirror without disturbing the resident. The life history and general behavior of *U. stansburiana* made this issue less troublesome than it might be with other species. *Uta stansburiana* are not nervous, or flighty, lizards. Residents occupy small territories and patrol often so as to prevent incursions from neighbors, and to switch ambush locations. So if residents are disturbed during the setup of the mirror, they often will return to this location within a short time and respond to their image, or allow the setup near their new location.

In sum, the mirror technique used in the field elicited aggression from residents but has limitations, as do all methods of eliciting aggression in a field study. The mirror results in aggression only if and when the resident is viewing its mirror image, and demonstrates only a certain level of aggression and not all aggressive behavior patterns. Real, tethered intruders clearly force the resident to engage in intense combative behavior, yet may give a false estimate of their social status since they cannot chase away the intruder. Both methods can be used to peek into the lives of lizards, and we recommend the use of both to elucidate different aspects of lizard territorial behavior.

Acknowledgments.—We thank the NiBlack Research Scholars Program for providing funding to LAW and MLA during the field season. We also thank the Vest-Pigmon Ranch for continued access to their property. LAW thanks Sam and Juanita Bryant for providing housing during the long field season. Fieldwork was approved and carried out under permits issued by the OSU IACUC (AS-083) and the Texas Parks and Wildlife Department (SPR-1007-1466) to MLA and SFF.

Applicability of "Tablet" Computers for Use by Field Biologists

Aside from traveling to and from their study sites and answering emails, three of the most time-consuming things that field biologists do are to (1) write field notes, (2) enter information onto field data sheets, and (3) transcribe those data sheets into Excel, Access, or another database program. Given that the concept of "spare time" is an unknown term to most biologists, any means of saving time in recording data in the field would seem to be highly desirable. In addition, any mechanisms that can make it easier to either retrieve information from field notes efficiently or that minimize errors in data entry are also quite valuable.

Although electronic aids such as micro tape recorders and PDA's have been used in the past for recording field data, the recent explosion of availability of small, highly portable "tablet" computers (i.e., hand-held devices running the Android, Microsoft Windows 8, or Apple iOS operating systems) has made many more solutions available to field biologists. Here, I provide an evaluation of a variety of tablet computers in terms of their applicability for field biologists to record field notes and data under real-life conditions. Although funding constraints make this less than a fully-comprehensive review, I was able to test a wide enough spectrum of devices to provide at least a preliminary guide to determine whether these tablets can be used to make recording data in the field more efficient and less time-consuming than traditional paper notebooks or datasheets.

Methods

I tested seven devices ranging in price from US$199 to $449 (Table 1). Four of these are classified as tablet computers as noted above (Apple iPad 2, Asus Eee Pad Transformer 101, Samsung Galaxy Tab 7.0 Plus, and Samsung Galaxy Tab 8.9), one is a cell phone with multi-purpose capabilities (iPhone 4s), and two are media players that can double as multi-purpose devices (iPod Touch and Samsung Player 5). Each device was used by myself and several of my students in a variety of field situations in Arizona, Florida, Maryland, and Missouri for both general note-taking and day and night-time data entry. I timed how long it took to enter a set of field notes via a traditional field notebook and entered the same information under field conditions with each electronic device. This exercise was repeated by myself and two students to provide some indication of variation due to operator skill level.

Because these devices can serve purposes other than data entry, I also evaluated their ability to assist investigators in three areas; photography, reading the literature, and replacement of traditional field guides with electronic substitutes. Specifications for photographic capabilities are listed in Table 1. To determine the ability of these devices to replace or compliment standalone digital cameras, I took two photographs with each device, a close-up of a plastic model of a frog from approximately 30 cm away, and a landscape photograph of a marsh. I then asked a series of volunteers to rate these photographs as "good" (comparable to a standard digital camera), "acceptable" (not rated as highly as "good", but usable for PowerPoint presentations), and "unacceptable" (meaning the photographs were not usable in a professional setting). One additional photograph from a Canon Sx 230 digital camera with 12 megapixel resolution was included for comparison. All evaluations were from single-blind trials, where I knew the identity of the device responsible for each photograph, but the evaluators did not.

Evaluating the usefulness of these devices for reading the literature or as an electronic field guide was more subjective; for each device, I downloaded both Microsoft Word and Adobe Acrobat versions of manuscripts and reprints, respectively, and determined whether I could adequately read the material using that device. Devices were rated as "good", "acceptable", or "unacceptable", similar to the way that photographs were evaluated. Ratings of electronic field guides for reptiles and amphibians were based on use by myself or students under field conditions in Maryland and Florida, but detailed ratings were not attempted.

Results

Portability.—The tablets I tested ranged in size from easily transportable in a pants pocket or belt pouch (iPhone, iPod Touch, Samsung Player), to those that were large enough to require a small hip or backpack (Samsung 7 and Samsung 8.9), to those that required at least a small daypack (iPad 2 and Asus Transformer). I found that having a tablet in a pants pocket made me much more likely to use the device compared with having to carry the units in a hip pack or, especially, in a daypack. However, several of my students that used the iPad 2 in the field felt that this was not a serious inconvenience and that they would be more concerned about the accidental loss of a small tablet carried in a pants pocket. In any event, neither I nor my students felt that the weight of any of these tablets was overly burdensome under most field conditions, including inclement weather.

Screen Size and Visibility.—There was an obvious trade-off between screen size and portability. The units with the largest screens (iPad 2, Asus Transformer, Samsung 8.9) were the easiest screens to read and, to some degree, the easiest for data entry (but see below), but these tablets could only be carried in a daypack or hip pack. To a large degree, the need for the larger screens depends on the visual abilities of the user and the way the tablet was used in the field. For examples, even with my poor 20/40 vision (after correction), I had few problems inputting and reading field notes with the three smallest tablets (iPod Touch, iPhone, Samsung Player), but found these screens to be less than useful for entering data onto electronic data sheets, for looking up data on Excel-compatible files, or for reading Adobe Acrobat or Microsoft Word files.

An important consideration for the use of tablet computers in the field is their degree of visibility when exposed to bright sunlight. With few exceptions, current tablet computers have highly reflective screens that, while producing high quality images indoors, reflect so much ambient light that legibility is greatly reduced when used outdoors under sunny conditions

RICHARD A. SEIGEL
Department of Biological Sciences, Towson University
Towson, Maryland 21252, USA
e-mail; rseigel@towson.edu

(http://www.displaymate.com/IPS_Tablet_ShootOut_1.htm). Screens with higher levels of adjustable brightness can, to some extent, reduce this problem, but I found that all of the tablets tested had high enough screen reflectivity to make sunlight a significant issue during field tests. Qualitatively, the iPhone, iPod Touch, and Samsung 8.9 had the best screens under bright conditions and the Samsung Player and Asus Transformer had the worst, with their screens almost unreadable in bright daylight. Use of an aftermarket anti-reflective screen can reduce glare and may make tablet screens more useful during daylight conditions, but may not always be effective. Thus, users should be aware of this issue and try and test the tablet they intend to purchase under real-world conditions and not simply in an indoor store environment. In addition, some newly-released tablets (e.g., Asus Transformer Infinity, Kindle Fire HD) have either extraordinarily bright screens (Asus) or less reflective screens (Kindle Fire) that are designed for better visibility under daylight use. However, using a higher brightness level can also decrease battery life.

Virtual Keyboard and Data Entry.—All of these tablets offer an on-screen (virtual) keyboard which, while not well-adapted for typing lengthy material, can easily be used for entering field notes or for typing information into datasheets. Table 2 illustrates the time it took myself and two students to enter a text passage of 40 words and 168 characters into each of the tablets compared with the time to enter the same text into a standard sized field notebook with a pencil. Time differentials (positive if typing on the tablets took longer than writing by hand, negative if typing was faster) ranged from +18 to 77 seconds for myself, from +6 to 46 seconds for a graduate student, and from -13 to +44 seconds for an undergraduate student who was more accustomed to typing with a small virtual keyboard (i.e., this student was faster with two of the tablets than writing by hand).

The Samsung 7 had the fastest input times compared with a traditional field notebook, followed by the iPad 2 and Samsung 8.9. The Samsung 5 (which had the screen least visible under sunny conditions and the slowest processor) had the worst input times (Table 2). Both my students and I felt that the ability to customize the keyboard types (easily done on the Samsung and Asus tablets) was a significant advantage, allowing the user to find the keyboard type that he or she was most comfortable with. I found that a keyboard that had a separate row of numeric keys greatly facilitated data entry, compared with a keyboard that lacked this option.

Quality of Photographs.—I found taking photographs using these tablets to be fairly easy, especially once I had practiced a few times and became familiar with the controls, which are obviously very different from those of a standard digital camera. The

TABLE 1. Specifications and information on the tablets evaluated. All prices (US $) are as of July 2012 at common discount web sites. Specifications come from the manufacturer's web site. Camera resolution in megapixels. See text for discussion of camera ratings.

Device	Price	Diagonal screen size	Mass (g)	Camera resolution	Camera rating (G = Good, A = Acceptable, U = Unacceptable)
Apple iPad 2	$399	246 mm	613	0.92	Close up (N = 9): G(0%), A(100%), U(0%) Landscape (N = 6): G(0%), A(100%), U(0%)
Apple iPhone 4s	$299	89 mm	140	8.0	Close up (N = 9): G(56%), A(44%), U(0%) Landscape (N = 6): G(50%), A(50%), U(0%)
Apple iPod Touch (8 gb)	$199	89 mm	101	0.69	Close up (N = 9): G(0%), A(0%), U(100%) Landscape (N = 6): G(0%), A(33%), U(67%)
Asus Eee Pad Transformer 101	$399	257 mm	680	5.0	Close up (N = 9): G(20%), A(80%), U(0%) Landscape (N = 6): G(67%), A(33%), U(0%)
Samsung Galaxy Player 5	$220	127 mm	182	3.2	Close up (N = 9): G(0%), A(11%), U(89%) Landscape (N = 6): G(50%), A(50%), U(0%)
Samsung Galaxy Tab 7 Plus	$399	178 mm	345	3.0	Close up (N = 9): G(100%), A(0%), U(0%) Landscape (N = 6): G(67%), A(33%), U(0%)
Samsung Galaxy Tab 8.9	$449	226 mm	448	3.0	Close up (N = 9): G(100%), A(0%), U(0%) Landscape (N = 6): G(83%), A(17%), U(0%)

TABLE 2. Comparative times to enter a set of 40 words and 168 characters into either a standard field notebook using a pencil (scored as 0) versus the additional time (positive numbers) or reduced time (negative numbers) to enter the same text into a selected tablet. Thus it took 18 seconds more for RAS to enter the text into the iPad 2 than it did to write the text into a field notebook using a pencil. Sum is the total of both reduced and increased times, so smaller numbers for Sum indicates faster entry times compared with other tablets.

Tester	Hand	iPad 2	iPod Touch	Samsung 8.9	Samsung 7	Samsung 5	Asus Transformer
RAS	0	+18	+60	+23	+26	+77	+38
Grad Student	0	+45	+46	+8	+6	+31	+27
Undergrad	0	-13	-1	+24	-1	+32	+44
Sum	0	+50	+105	+55	+31	+140	+109

only substantive problem was encountered when taking photographs in bright sunlight, when the screen (viewfinder) was hard to see, especially for the Asus Transformer and Samsung 5 units. My students rated the Samsung 7 and 8.9 as having the best photographs of the plastic frog (equivalent to a macro photograph of a live animal), with all students rating the photograph as "good" for both devices, even rating these two tablets above the Canon digital camera used as a comparison (Table 1). The iPhone and Asus Transformer were rated from "acceptable" to "good", but the iPod Touch and Samsung 5 were both judged to be largely or entirely unacceptable based on this test (Table 1). The Samsung 8.9, the Samsung 7, and the Asus Transformer had the best performance on the landscape photograph, followed closely by the iPhone, iPad, and Samsung 5 (Table 1). Both photographs taken by the iPod Touch were rated as the worst of these devices, which is unsurprising, as it has the lowest camera resolution of any of the tablets tested.

Availability of Critical "Apps".—Regardless of price, size, and screen quality, it is the availability of "apps" (software programs for tablets) that largely determines the utility of these devices. Because the iPad and iPhone have such large market shares, the availability of apps tends to be more comprehensive for these devices. However, the popularity of new Android-based tablets such as the Amazon Kindle Fire and Nexus 7 has resulted in many new apps being introduced for this platform as well. All apps noted below are available for Apple devices via the iTunes Store (www.apple.com/iTunes) and for Android devices via Google Play (https://play.google.com/store).

I divided the apps available for both platforms into two general categories; productivity software and field-specific software. Below, are brief overviews of both categories. However, the reader should keep in mind that new apps are introduced almost daily and older packages are updated frequently, so this should be used as an introduction rather than a comprehensive review.

Productivity Apps: Word Processing and Spreadsheets.—Field biologists wanting to use tablets for recording field data will certainly need apps that fill the roles taken by such standards as Microsoft Word and Excel. I tested several such apps for both the Apple and Android platforms. For the Apple (iOS) platform, the most comprehensive packages are Pages (Microsoft Word compatible) and Numbers (an Excel compatible spreadsheet). Both integrate extremely well with the iPad and iPhone, are not overly expensive ($9.99 each), and, after some experience using a touch screen instead of a mouse, are quite easy to use. Other Word and Excel replacements for the Apple products include Documents to Go ($16.99 for both word processing and spreadsheet apps), Office 2 HD ($7.99 for the package), and Quick Office ($19.99). I found Pages and Numbers to have a very good combination of features and ease of use, but two of my students using an iPad 2 for field data entry preferred Documents to Go or QuickOffice. Thus, this will be a matter of individual preference.

Word and Excel compatible apps are quite common on the Android platform as well. I tested four such programs for this review; Documents to Go ($14.99), OfficeSuite Pro ($14.99), Kingsoft Office (free), and QuickOffice ($19.99). I found that Kingsoft Office worked as well as the other packages and was free. Both the Apple and Android word processing and spreadsheet apps worked well for entering data and, when combined with a physical keyboard (see below) are useful for composition of manuscripts. However, they still lack certain features (most notably "Track Changes") that will allow tablets to replace a traditional laptop. This will likely change as these apps become more capable; the most recent release of Apple's Pages app (1.7.1, late fall 2012) does allow a form of Track Changes to be implemented, and other apps may well do the same. In addition, full versions of Microsoft Office are now available on the new Windows RT and Windows 8 tablets that are just entering the market in late 2012.

An important consideration for use of all of these apps is how to transfer data files to your main computer and how to guard against potential loss of data, and the ease of this does vary widely among devices and packages. Several of the Android devices (the Samsung Galaxy Player 5, the Galaxy 7 Plus, and the Asus Transformer) have micro-SD card slots where data can easily be stored and then copied directly to a laptop or desktop. I found this to be the simplest solution to backing up my data on the tablets. For devices that lack such a capability (or if you prefer a different method), data can be transferred via email (all devices), via iCloud (Apple devices only), or via a cloud-based service such as Dropbox (https://www.dropbox.com/) or Google Drive (https://www.google.com/intl/en_US/drive/start/index.html). Indeed, one reason for my preference for Kingsoft Office was the ease with which this app integrated with Dropbox. I experienced no loss of data under actual field conditions using either of the Apple products or using Kingsoft Office for the Samsung devices, but did find that some of the other Android apps made saving files less than transparent. Thus, being thoroughly comfortable with how the selected apps save data files is something that should be done before recording data in the field.

Field Apps.—Although applications designed specifically for field herpetologists remain relatively small in number, there are several useful apps available. For North America, the Audubon Nature series (US $4.99 each) is available for the Apple devices (at least for reptiles and amphibians) and has been used extensively by some of my students. A more international app, Turtles of the World (US $9.99, also for the Apple devices) contains color photographs, range maps, and ecological information on all known species of turtles (500+ species and subspecies), with the text based on Ernst and Barbour (1989). Although I found fewer herpetological apps available for the Android platform, development of additional field apps are ongoing, so more choices should be available as the use of tablets expands.

Beyond herpetological-specific apps, there are a number of useful programs available for both the Apple and Android devices. For North America, these include iBird Plus/Pro (Apple via iTunes and Android via Google Play) and Mammals of North America (Android). Such apps can be valuable not only for personal use, but for use in field classes as well.

For GPS-enabled devices (e.g., the iPhone, Samsung Player, Samsung 8.9, and Asus Transformer), there are a number of GPS apps that have considerable advantages for field workers. I tested the iPad app Motion-X GPS HD (US$1.99 on the iTunes store) and the Android app GPS Essentials (free on the Google Play site). Each app did an excellent job of taking advantage of the larger screens available on the iPad, Samsung 8.9, and Samsung Player to make tracking of routes, recording waypoints, and displaying compass headings very simple and easy to do. While not perhaps replacing stand-alone GPS units, having one less device to buy and carry was quite convenient.

Apps for reading the literature.—Given that most reprints today are distributed as Adobe Acrobat files (.pdf files), having an app that allows downloading and reading your reprint files greatly enhances the utility of tablet computers. Fortunately, there are a number of relatively inexpensive and easy-to-use apps that do just this for both the Apple and Android platforms.

Examples include Adobe Reader (both platforms), GoodReader (Apple), and most of the word-processing apps noted above. The Kindle reader app from Amazon is also a very capable reader of Acrobat files. In addition, the widely used reference management program Mendeley has a version available for the Apple iPad and iPhone/iPod Touch that can synch with your desktop files, giving you access to your entire reprint library.

With the exception of the Galaxy Player 5, I found all of these devices displayed reprints and text files quite well. The larger screens of the Asus Transformer, the iPad 2, and the Galaxy Tab 8.9 were the best for reading reprints and text documents (all rated as "good"), whereas the small screen and low resolution of the Player 5 made reading problematic and this device was rated as "unacceptable" for this purpose.

Accessories.—There are a number of accessories for tablets that, while not strictly required, are important in making tablets more useful and extending their life in a field environment. The most obvious of these is a good case, clearly important in protecting tablets when used in the field. Cases, available for all tablets in a very wide variety of levels of costs (ca. $20–100), protection (including waterproof cases), and features are widely available from both web sources (Amazon) and from retail sellers (Best Buy, Office Depot, etc).

Another valuable accessory is a physical keyboard. Although the on-screen (virtual) keyboard has the advantages of being always available and requiring no additional purchase, a physical keyboard can transform a tablet computer from a device that is used primarily for "consumption" (reading, looking at field apps, etc) to one that enhances productivity as well. Indeed, most of this paper was written on such keyboards while I was in the field. External keyboards come in two basic kinds; a docking keyboard that links to the tablet through a dedicated port (Android platform) or a Bluetooth keyboard which connects to the tablet wirelessly (Apple and Android devices). Both have pros and cons. Docking keyboards ($50–140) eliminate the need to make a Bluetooth connection (which can reduce battery life and sometimes be problematic in my experience), and often have additional ports for connecting memory cards or speakers. However, external Bluetooth keyboards are cheaper ($30–70), lighter, and can be used with multiple devices. In addition, there are a number of keyboard "folios" that, while not physically connecting to tablets through a port, contain both a case and a keyboard and make a combination that is very similar to a laptop.

Battery Life.—I did not formally test battery life for these devices, but used all of these in the field over about a 12 month period. Battery life only became a concern if I was making heavy use of 3G, WiFi and/or Bluetooth technologies or if I forgot to charge the tablet when battery life fell to < 20%. Qualitatively speaking, I found the Apple devices to have the best battery life and the Android devices to be somewhat less capable, but rarely found myself restricted in this regard. In general, if the WiFi and the Bluetooth connections were kept off except when needed for internet or keyboard connectivity, I could use the tablets 2-3 hours per day and only have to recharge the batteries every second or third day. Battery life could be further extended by powering down the tablet (as opposed to putting it to sleep) at night or during long periods of inactivity. In addition, purchasing a mobile power adapter for use in a vehicle makes charging while on the road quite simple and portable power supplies to allow recharging while in remote areas are also available (e.g., http://www.richardsolo.com/iPad_Accessories.html).

Conclusions

As an admitted "technophile", my interest in adopting tablet computers for field use was quite high. However, after extensive testing by both myself and my students, we have found that these devices are, to a large degree, the modern electronic equivalent to the Swiss Army Knife. The ability to record field notes and data, take and display reasonable-quality photographs, use electronic field guides, record GPS locations, write papers, and read electronic reprints has made a tablet computer an essential piece of field gear for myself and several of my students.

This is not to say that tablet computers do not have limitations, sometimes important ones. The most critical of these are (a) cost, (b) screen readability, and (c) weight. Of these, the first two are probably most important, as the total mass of a digital camera (220 g for my Canon SX 230), field notebook (113 g for a Rite in the Rain notebook), and metal clipboard (700 g) for recording data sheets is very close to or even greater than some of the tablet computers tested here (Table 1). Other constraints to keep in mind are the habitat conditions where field work takes place (e.g., working in monsoon conditions in wetlands may make using these devices impractical) and whether tablets can be recharged at least every few days.

Whether the multi-functional nature and convenience of a tablet computer is worth the $199–450 cost is a personal decision that depends on available funding and the conditions under which the tablet will be used. However, the wide range of costs, sizes, and screen readability suggests that there are many cases when the "match" between cost and need will be a good one. That being said, I strongly advise those looking at a tablet for field use to be sure to either test the unit under field conditions before buying or to purchase a tablet from a vendor that has a reasonable return policy. That would help insure that the purchase is one that will fit the exact needs of the individual.

Acknowledgements.—I thank my current and former students for helping to test tablets in the field, especially Kaite Anderson, Nathan Byer, Teal Richards-Dimitrie, Ben Seigel, and Meagan Thomas. Funding for purchasing some of these tablets was provided by Towson University, Exelon Corporation, and the National Park Service. Comments on the ms were provided by Teal Richards-Dimitrie, Kaite Anderson, Nathan Byer, Nadia Seigel, and two anonymous reviewers.

HERPETOCULTURE

This section offers a publication outlet for manuscripts involving amphibians and reptiles in a captive environment—public or private. Subjects appropriate for this section include, but are not restricted to, the following:

- Novel techniques for maintenance and reproduction of live herpetofauna
- Genetic management of captive populations
- Legal issues in herpetoculture and animal trade: laws, regulations, permits
- Reviews of tools, equipment, technology, enclosures, etc.
- Safety protocols for working with dangerous species
- Policies and procedures related to preventing transmission of pathogens

Manuscripts that deal exclusively with veterinary medical subjects generally are not appropriate for this section, but consult Section Editor if in doubt.

Manuscripts, ideas, or questions should be directed to the Herpetological Husbandry Section Editors, Brad Lock (block@zooatlanta.org) or Wulf Schleip (wschleip@leiopython.de). All manuscripts will undergo external peer review. For detailed instructions on manuscript preparation, please consult the SSAR web page at: http://www.ssarherps.org/pages/HRinfo.php. When reporting on captive held animals, please also consider the *Guidelines for Use of Live Amphibians and Reptiles in Field Research*, accessible at: http://www.ssarherps.org/pages/HRinfo.php

For authors whose native language is not English and who might require assistance with manuscript preparation, we invite you to consult SSAR's Presubmission Manuscript Review service: http://www.ssarherps.org/page/presub.php.

In addition to conventional manuscripts, we will also publish brief notes based on limited observations of captive animals. These can be considered analogous to Natural History Notes and should be formatted the same way. Please consult that section for formatting guidelines. Subject matter examples include: breeding, courtship, clutch/litter size, gestation, growth, age at first reproduction, longevity, feeding preferences/techniques, thermal biology, unusual behaviors, and so forth. Contributions are welcome from all persons who work with captive amphibians and reptiles, including zoo biologists, private herpetoculturists, and institutional professionals.

Herpetological Review, 2013, 44(1), 86–89.

Observations on the Endangered Iranian Zanjan Viper, *Montivipera albicornuta* (Squamata: Viperidae), in Captivity and in the Wild

The Zanjan Viper, also known as the Iranian Mountain Viper, or Zig-Zag Mountain Viper (*Montivipera albicornuta* [Nilson and Andrén, 1985]) is a small viper endemic to the Zanjan Valley and surrounding mountains in northwestern Iran (Latifi 1991; Rastegar-pouyan et al. 2008). The type locality is Abhar in the Zanjan Valley (36°8'N, 49°13'E) between Tabriz and Teheran (McDiarmid et al 1999; Fig. 1). This species is generally associated with rocky habitats, including rock walls, scree, and cliff edges within the Valley. It is not present in the steppe-like habitat or agricultural areas of the valley floor. Nilson (2008) outlined the major threats to this species: over-collecting by commercial snake hunters for its use in serum production, resulting in a corresponding decline in populations, and livestock grazing. He stressed that the habitat appears to be in suitable condition, but since the snake is currently marginally protected throughout its range, there is an urgent need to restrict or, better yet, prevent collection. Nilson further said that this viper is not considered to be a great threat to people because it lives in a remote area at elevations of around 2500 m. The population is listed as vulnerable in the Red List of IUCN and is decreasing (Nilson 2009). Its conservation status in Iran—according to the Environmental Protection Council No. 168 about hunting and fishing of wild animals—is protected, but enforcement is difficult. Two areas have

viper populations: Anguran Wildlife Refuge and Sorkhabad Protected Area in Zanjan Province (Kalantary and Parchiyanlu 2009) (Figs. 2, 3).

McDiarmid et al. (1999) and Roy McDiarmid (pers. comm.) stated that the taxonomic allocation for this taxon is confusing. Nilson and Andrén (1985) placed it in the *Vipera raddei* group. Schätti et al. (1991) suggested that *Vipera albicornuta, V. latifi*, and *V. raddei* (including *kurdistanica*) might represent allopatric populations of one species. Golay et al. (1993) treated

albicornuta and *latifii* as subspecies of *Vipera raddei*. Because there has been some controversy about several of these taxa, McDiarmid recommends following the most recent paper (Rajabizadeh et al. 2011), which recognizes *albicornuta* as distinct and shows its range as separate from the other Iranian species in the *Montivipera raddei* group, so we use this name here.

In older Iranian literature on venoms and snakebites, many *Vipera* species, including this taxon, were considered *Vipera xanthina* or *V. xanthina* ssp. (Mallow et al. 2003). Nilson et al. (1999) erected a new subgenus *Montivipera* within the genus *Vipera;* nine taxa are represented including *M. albicornuta*. We consulted Andrén and Nilson (1979), Latifi (1985), Nilson and Andrén (1986), Mallow et al. (2003), and Phelps (2010) for descriptions of *M. albicornuta,* especially color and pattern morphs. We examined diagnostic characters of three of our snakes that died shortly after arrival and these fit the description published by Mallow et al. (2003). Total length of one of our snakes (male) was 81.2 cm and tail length was 5.6 cm; Mallow et al. (2003) recorded 66 cm as maximum size in a male.

The coloration and pattern in some of our specimens correspond to the snake pictured in Latifi (1985; plate 4, # 8, *Vipera xanthina*). He includes the snake in his list as the Zanjani Viper in Zanjan Province (19). Fig. 4 shows a specimen collected at the type locality.

Today this species is vulnerable and has essentially vanished from parts of its range due to both the destruction of its natural habitat and the over-collecting of snakes for the production of antivenin. In 1958, the Razi Institute started to produce antivenin and the first serum was issued for therapeutic use two years later (Latifi 1978). In 1984, Latifi described venom extraction and antivenin production. Studies before taxonomic changes were published on Iranian vipers (*Vipera albicornuta, V. latifii, V. raddei*) were based on the taxon *Vipera xanthina* (Mallow et al. 2003). Latifi and Farzanpay (1973) said that between 1969 and 1973, about 1680 snakes were collected for Razi. Up to 1978, 4400 vipers were used (Latifi 1978). Mallow et al. (2003) describe the production of antivenin in detail. Today, Razi produces a polyvalent antivenin to cover Iranian vipers. Abolfazl Akbari (pers. comm.) stated that over 2000 venomous snakes are brought to Razi Institute annually for venom extraction. Kian (pers. observ.), who worked at Razi, saw the following species used for antivenin production: Central Asian Cobras (*Naja oxiana*), Levantine Vipers (*Macrovipera lebetina*) (200–250 individuals), and the rest mostly comprised Latifi's Viper (*Montivipera latifii*), Caucasian Pit Viper (*Agkistrodon halys*), Transcaucasian Meadow Viper (*Vipera ursinii*), Persian Horned Viper (*Pseudocerastes persicus*), Saw-scaled Viper (*Echis carinatus*), and Zanjan Mountain Viper. Gasperetti's Viper (*Cerastes g. gasperettii*) was not used for venom extraction.

There are three main reasons for setting up a colony of *M. albicornuta* and other species at Razi Institute: to eliminate the need to purchase snakes from local collectors for antivenin production, to increase numbers by improved captive management and expanded captive breeding, and to decrease mortality rates.

Captive Management

In 2009 and 2010, respectively, four specimens (two adult pairs) and 10 adult individuals (three females and seven males) were collected from Zanjan Valley to begin a captive colony to study reproductive biology and behavior (Figs. 5, 6). The first group was kept at the Razi Institute and the next at University of Tehran. Husbandry and captive protocols follow those outlined for Latifi's Viper (*Montivipera latifii*) described earlier by Kian et al (2011). During August 2009, two adult pairs were housed in a vivarium with aluminum gauze on top for ventilation (120 cm length × 60 cm width × 50 cm height). In 2010, two adult pairs were housed together in these enclosures, three males and one female in another, and two males in the third. The substrate was peat moss and hiding places were provided. The temperature within the vivaria ranged from 30 to 32°C under the heat lamp, set to mimic daylight cycles during the day, and allowed to cool at night without supplemental heat to 26–28°C. The humidity was between 40–50% and every week the enclosures were sprayed with warm water. Sexes were tentatively assigned based initially on tail ratio and later validated by observation of male copulatory organs. Nail polish was used to mark the animals.

Feeding.—The diet for this species in the wild consists of insects, grasshoppers, lizards, and mice (Mallow et al. 2003). Newborn and adult mice (*Mus musculus albinus*), newborn rats (*Rattus norvegicus berkennhout*), and lizards (*Mesalina watsonana, Eumeces schneiderii*) were offered once a week. Laboratory mice were the most common food items for this species. They were selected to decrease the risk of endoparasitic infection. In 2010, the food items were supplied with Rep-Cal Herptivite Multivitamin (Rep-Cal Research Lab, Los Gatos, California). There was competition during feeding. In some cases, snakes struck each other during predatory episodes.

Ecdysis.—Shedding depends largely on environmental temperature and amount of food intake; our snakes generally shed between one to two weeks, although there were occasions where ecdysis occurred at intervals of several months. Adequate moisture was provided by spraying water into vivaria every other day. Sometimes snakes had incomplete sheds so they were soaked for 20 minutes to facilitate complete removal of the skin.

Temperatures and Light Cycle.—Temperature records from the site of collection are as follows: frost may begin in October and last until early April. The coldest months are January and February with average temperatures of 0°C. In January, temperatures were as low as -5°C. The average temperature in July and August is 24°C but may rise to 31.7°C during the latter month.

We believe that hibernation is necessary for this species to reproduce, so males and females were separated and placed in hibernation. Prior to hibernation, the range of weight for seven males was 86–159 g (mean 107 g), and three females was 96–160 g (mean 122 g); the snakes were not weighed after emergence to reduce potential stress. On 15 November 2009, feeding was discontinued. After seven weeks, the temperature of the vivaria was lowered to 10°C and the supplemental lamps were removed. The cooling period was three months and temperature hovered between 8–10°C throughout this span. Food was not offered but water was provided. Three months later, the lighting cycle was increased to three hours and thus we began increasing day length until 12 hours of light per week were reached. Natural sunlight was allowed to penetrate into the room after snakes emerged from hibernation. Thirty-five days later, after emerging from hibernation, males and females were placed together to elicit courtship and copulation. During May 2010, courtship behavior by the male was seen but mating was not observed. Male combat was not seen. Importantly, the survival ratio of all the hibernated snakes in two years was 100%.

Acknowledgments.—This project could not have succeeded without the devoted technical help of University of Tehran staff. The

authors are grateful to Shohreh Teymurzadeh, Roozbeh Behrooz, and Nima Khalilbeigi for their help and encouragement. For various courtesies, we thank Judith Block, Polly Lasker, and Roy McDiarmid.

Larval Growth and the Potential for Head-starting of Eastern and Ozark Hellbenders (*Cryptobranchus alleganiensis alleganiensis* and *C. a. bishopi*)

Eastern Hellbenders (*Cryptobranchus alleganiensis alleganiensis*) are large, paedomorphic salamanders found across the midwestern USA east to the Appalachian states of Pennsylvania and New York and south to northern Georgia (Petranka 1998), with western populations of the Ozark Hellbender subspecies (*C. a. bishopi*) confined to Missouri and Arkansas. Hellbender populations across this geographic range are experiencing significant declines largely characterized by an overall lack of recruitment, with populations composed almost entirely of older age classes (Wheeler et al. 2003). The Ozark Hellbender (*C. a. bishopi*) recently has been listed as federally endangered.

Detailed descriptions of early developmental stages (eggs and larvae) are essential for understanding life history traits for species of conservation concern. Although growth rates for adults (older age classes) have previously been reported (Horchler 2010; Peterson et al. 1988), information on growth rates at the vital gilled larval stages is surprisingly lacking in the scientific literature for this cryptic species. Hellbender larvae are rarely encountered during surveys, possibly due to high mortality rates, observer bias, or their occurrence in small interstitial spaces in gravel beds (Nickerson and Mays 1973; Williams et al. 1981). Although a select few sites within their range do harbor this early life stage in moderate numbers (Hecht-Kardasz et al. 2012), attempts at measuring growth based on recaptured larvae have proved unsuccessful. Recently, the importance of secure larval habitat has been proposed as a major factor for maintaining large adult populations (Nickerson et al. 2003). Successful captive management strategies for this species should incorporate information concerning life-history traits to maximize head-starting recovery programs.

The primary purpose of this study was to quantify growth rates of Eastern (*Cryptobranchus alleganiensis alleganiensis*) and Ozark Hellbenders (*C. a. bishopi*) at an early life stage, six

**Corresponding author*

months post-hatching, to determine the potential for rearing larvae under laboratory conditions. A secondary goal was to compare the growth rates among clutches from several populations and two subspecies to examine potential intrinsic differences in development of gilled larvae. This information should be useful for captive management decisions. For example, if clutches differ substantially in growth, further studies should examine whether different dietary regimes might be required for salamanders from different populations.

Laboratory Rearing/Analyses.—Larvae were hatched out of egg masses collected from the field on 10, 13, and 30 September and 18 November 2002, with one clutch each from the following sites: Davidson River, North Carolina; Coopers Creek, Georgia; Gasconade River, Missouri (eastern subspecies); and the North Fork of the White River, Missouri (Ozark subspecies), respectively. Following hatching, individuals were measured (TL mm) with calipers weekly on the same day for 24 weeks (~6 months) from 5 October 2002 to 3 April 2003. Larvae were kept at 19–21°C and were housed individually in aerated plastic containers (34.5 × 21.6 × 10.6 cm; 5.4 liters) for the majority of the study with de-chlorinated tap water, which was changed three times per week. Because egg masses were collected at different stages of development, we standardized stages based on morphological features defining each stage (Smith 1912) at hatching, which occurred on the following dates: 5 and 14 October and 4 and 25 November 2002 for Eastern Hellbenders from the Davidson River, Coopers Creek, and Gasconade River, and Ozark Hellbenders from the North Fork of the White River, respectively. Hatching success was highly variable (5–95%), with mortality associated with presence of a fungus that attacked the egg mass, identified as *Saprolegnia*. Consequently, sample size for each clutch was also highly variable: Davidson River N = 111, Coopers Creek N = 9, Gasconade River N = 66, and North Fork of the White River N = 145. Growth rates among clutches (rivers) were compared using a Kruskal-Wallis test (MINITAB).

Larval diets were adjusted as the larvae changed in size. Larvae were initially fed a variety of live food items including blackworms (*Lumbriculus variegates*), mayfly nymphs (*Stenonema* sp.), cladocerans (*Ceriodaphnia* sp., *Simocephalus* sp.), and chopped earthworms (*Lumbricus terrestris*). Once larvae obtained a TL of 60–80 mm, they readily consumed small crayfish (*Orconectes* sp.) (3.5–5.1 cm). At 80–100 mm they were successfully fed small darters (*Etheostoma* sp.) (approximately 3.8 cm TL); however, blackworms made up the majority of their diet at this size.

Growth Rates.—Intra-clutch size variation during weekly measurements was so small that even slight differences among populations were statistically significant. For example, there was a statistically significant difference in average size of larvae among clutches at week 3 (Fig. 1) even though the actual difference was only about 1 mm (Kruskal-Wallis test: H = 12.3, d.f. = 3, $P = 0.006$). By week 13, the larvae of the Eastern Hellbenders from Missouri and Georgia were noticeably smaller than larvae from North Carolina and Ozark Hellbenders (H = 29.1, d.f. = 3, $P < 0.001$). However, this difference disappeared over the next two months and growth rates were strikingly similar among populations and subspecies (Fig. 1).

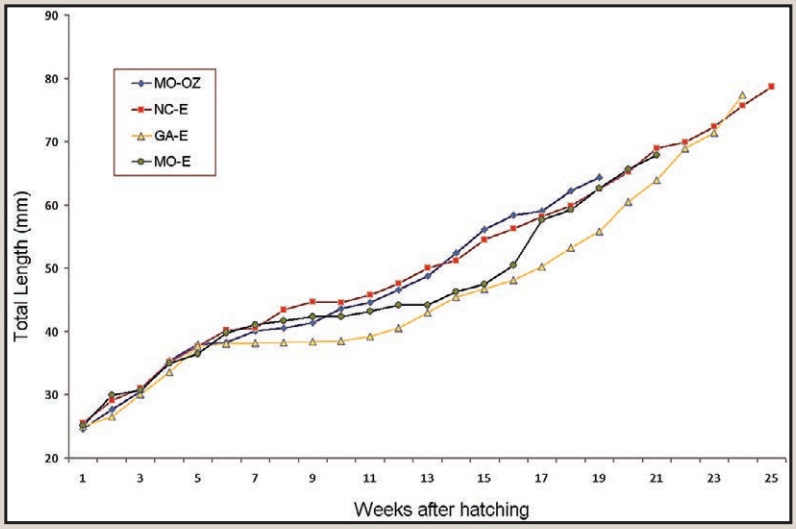

FIG. 1. Comparison of populations for weekly growth following hatching. SEs are omitted for the sake of clarity. E = eastern subspecies (*Cryptobranchus a. alleganiensis*), OZ = Ozark subspecies (*C. a. bishopi*). MO-Ozark (N = 145–119); NC-Eastern (N = 111–47); GA-Eastern (N = 9–4); MO-Eastern (N = 66–29). Preceding numbers (in parentheses) represent the range in sample size per group measured weekly over the course of the study.

PHOTO BY ADAM CRANE

FIG. 2. Typical *Cryptobranchus* larva showing recent absorption of yolk, gill structure, and complete limb development.

We observed an overall difference in post-hatching mortality among clutches, with the Missouri Ozark clutch having the lowest post-hatching mortality (North Carolina eastern = 58%; Georgia eastern = 56%; Missouri eastern = 44%; Missouri Ozark = 18%). A critical period of development in which unusual mortality occurred is the period of change in nutrition (yolk-based to active feeding) (Smith 1912). We noted minimal mortality during the period in which the yolk is exhausted. Directly following this period, a few individuals had trouble eating and eventually starved. However, the majority of larvae did not have difficulty switching to live food and developed fully (Fig. 2).

Developmental abnormalities were seen only in larvae from the clutch of Eastern Hellbenders from Missouri. These included severely malformed (curved) spines (N = 2), tails (N = 4), and bloating (N = 15). Samples of malformed larvae were examined at the Veterinary Medical Diagnostic Laboratory in Columbia, Missouri. They reported that the larvae were infected by common bacteria (*Staphlococcus* sp. and *Aeromonas* sp.), but found no evidence of potentially harmful fungi or other parasites. The larvae were also diagnosed with hepatic lipidosis (fatty liver disease). Malformed larvae appeared to have great difficulty swimming and this disease presumably was contracted as a result of not being able to feed.

Successful Head-starting.—The similarity in larval growth rates suggests that there are no major intrinsic differences among the populations of Eastern and Ozark Hellbenders at this critical early stage. Laboratory-reared larvae had greater ranges in size in this study than those reported by Grenell (1939) and Smith (1912), who studied a combination of laboratory-reared and field-caught larvae (3–9 months old: Grenell = 35–60 mm, 6.5 months post hatching; Smith = 57 mm; this study = ~45–80 mm). However, growth rates for amphibians often are higher in the laboratory than in nature, and laboratory growth rates should be interpreted as measures of growth potential (physiological capabilities) (Jorgensen 1992). For example, laboratory-reared *Bolitoglossa subpalmata* individuals had twice the monthly growth rate as seen in nature (Houck 1982; Vial 1968). Laboratory-reared hellbender larvae begin to lose their gills at an earlier time than those in nature based on our observations. Faster growth under laboratory conditions could be the result of higher temperatures than those found in nature or could result from laboratory-reared larvae receiving more food and experiencing lower activity levels than would be required for actively foraging for food in the field.

This study demonstrates the efficacy of rearing hellbender larvae and monitoring development under relatively simple laboratory conditions. These results are encouraging since gills are typically not lost until 1.5–2 years after hatching or at ~100–130 mm TL (Grenell 1939; Smith 1912), indicating larvae reared in a laboratory setting can readily obtain this transformation size at an earlier age than observed in nature. Conservation efforts for this species can apply these accelerated growth rates and developmental ontogeny into their management programs.

Acknowledgments.—We thank Chris Barnhart for the use of his AHAB system for initial egg rearing of these individuals. Individuals were collected as part of another study with the permission of the Missouri Department of Conservation (#11505), North Carolina Wildlife Resources Commission (#2002-ES286), and Georgia Department of Natural Resources (#14781). Individuals were maintained in the laboratory following Animal Care guidelines. Funding was provided by the U.S. Fish and Wildlife Service, Missouri State University Department of Biology and Graduate College.

HERPETOCULTURE NOTES

TESTUDINES — TURTLES

***MAUREMYS ANNAMENSIS* (Vietnamese Pond Turtle). LOCALITY AND LONGEVITY.** *Mauremys annamensis* is a rare geoemydid turtle native to central Vietnam (Nguyen et al. 2009. Herpetofauna of Vietnam. Edition Chimaira, Frankfurt am Main, Germany. 768 pp.). The development of wetlands and intensive collection for the wildlife trade have resulted in the near total extirpation of *M. annamensis* from the wild (TCC [Turtle Conservation Coalition] 2011. Turtles in trouble: the world's 25+ most endangered tortoises and freshwater turtles – 2011. IUCN/SSC Tortoise and Freshwater Turtle Specialist Group, Turtle Conservation Fund, Turtle Survival Alliance, Turtle Conservancy, Chelonian Research Foundation, Conservation International, Wildlife Conservation Society, and San Diego Zoo Global, Lunenburg, Massachusetts. 54 pp.). Although large numbers of specimens within the wildlife trade have been documented, since 1939 only two individuals outside of captivity have been recorded in the literature. A hatchling was recovered in 1993 from the artificial well of a village in Gia Lai Province (Parham et al. 2006. Herpetol. Rev. 37:239). The second, a subadult, was captured in a wetland in Quang Nam Province in 2006 (TCC 2011, *op. cit.*).

As a consequence of its scarcity, little is known about the life history of *M. annamensis*. Most aspects of the species' biology, such as life span, have only been inferred through observations of captive individuals. Snider and Bowler (1992. Longevity of Reptiles and Amphibians in North American Collections, 2nd ed. SSAR Herpetol. Circ. 21:1–40) listed an age of 23 years and 11 months for the oldest known individual, a wild-captured female residing at the Columbus (Ohio, USA) Zoo in 1990. This record has continued to be reported by subsequent authors (e.g., Slavens and Slavens 2000. Reptiles and Amphibians in Captivity: Breeding—Longevity and Inventory [current January 1, 1999]. Slaveware, Seattle. 400 pp.). Herein, we provide the first published details regarding the acquisition and history of this turtle, update the longevity record, and discuss the significance of this specimen.

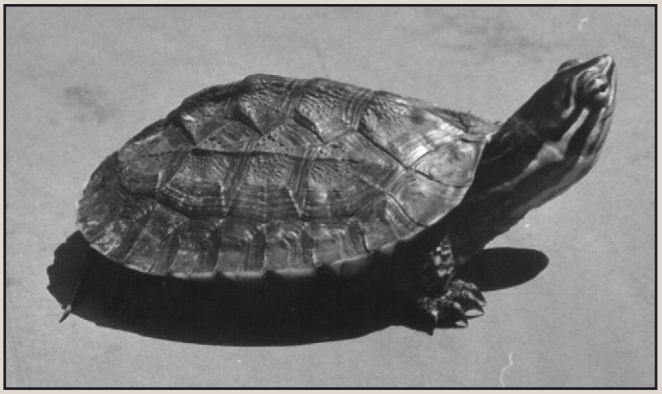

FIG. 2. An undated photograph, presumably from the late 1960s, showing the juvenile *Mauremys annamensis*. Photo from the image archives of the Columbus Zoo and Aquarium Reptile Department.

PHOTO BY JEFFREY E. DAWSON

FIG. 3. The female *Mauremys annamensis*, the oldest known individual of this species, at the Columbus Zoo and Aquarium in September 2012.

U.S. Navy corpsman James "Jim" Lowery was stationed in the Republic of Vietnam (South Vietnam) from 12 September 1965 to 11 September 1966. Assigned to a preventive medicine unit, Lowery's primary duty was mosquito surveillance, but he and the other personnel also conducted surveys of local wildlife, collecting potential disease vectors and other specimens, including representatives of herpetofauna. These collections resulted in papers on the natural history (Johnson and Lowery 1968. Herpetologica 24:336–338) and distribution (Johnson 1970. Herpetologica 26:527–532) of herpetofauna in Quang Nam Province. Prior to his military service, Lowery had worked at the Columbus Zoo. While in South Vietnam, he maintained contact with Louis Pistoia, then Curator of Reptiles and Amphibians at the zoo. Through his communications with Pistoia and military officers, Lowery (pers. comm.) arranged for some of the animals that he caught to be sent live to the zoo.

During a mosquito-collecting mission in late January or early February 1966, Lowery (pers. comm.) captured a juvenile *M. annamensis* in a ca. 0.6 m wide, slow-flowing, low-turbidity stream surrounded by a meadow. The stream was located ca. 8 km NW of the city of Da Nang, in Quang Nam Province (Fig. 1), an area which includes several low-lying sloughs and tributaries of the Phu Loc River (Danang URENCO [Danang Urban Environment Company] 2003. Vietnam Three Cities Sanitation Project: Danang Sub-project, Vol. 10: Environmental Impact Assessment. Report to the World Bank. http://www-wds.worldbank.org/servlet/WDSContentServer/WDSP/IB/2003/10/10/000094946_0309300404042/Rendered/PDF/multi0page.pdf). The turtle was discovered during daylight hours floating among vegetation along the edge of the channel.

In 1997, Da Nang was separated from the rest of Quang Nam Province to become an independent, centrally-controlled municipality. Today, Da Nang is the third largest city in Vietnam. The approximate collection locality of the turtle is now incorporated into the city and encompasses parts of An Khe, Hoa Minh, and Thanh Khe wards. Since the collection of the turtle, the area has been heavily developed and the watercourses have been impacted by the filling of low-lying areas, channelization, and pollution (Danang URENCO 2003, *op. cit.*). Due to the current unsuitability of habitat, it is unlikely that *M. annamensis* continues to inhabit the area where the turtle was collected.

The specimen of *M. annamensis* was accessioned into the Columbus Zoo's collection on 2 June 1966 (Fig. 2). Unfortunately, little specific information is available regarding the early husbandry of the turtle (however, for an overview of the diet and housing developed for freshwater turtles at the zoo during the late 1970s and 1980s, see Goode 1991. *In* Beaman et al. [eds.], Proceedings of the First International Symposium on Turtles and Tortoises: Conservation and Captive Husbandry, pp. 66–76. Chapman University, August 9–12, 1990). In the 1990s, the turtle was loaned to the late Michael Ewert; data resulting from his work on reproduction in this species were later included in Ewert et al. (2004. *In* Valenzuela and Lance [eds.], Temperature-dependent Sex Determination in Vertebrates, pp. 21–32. Smithsonian Books, Washington, D.C.). Ewert returned the turtle to the zoo on 11 June 2002.

To our knowledge, this turtle was the only living representative of *M. annamensis* in the United States for several decades after 1966. Additional specimens of the species did not appear in the U.S. through reptile importers until the late 1980s and early 1990s (pers. obs.). The Columbus Zoo acquired five additional individuals in 1990 and received another three individuals on breeding loan later that year. More turtles were obtained over the next few years. Propagation of the species at the zoo first occurred in 1991, with successful reproduction also occurring in subsequent years (Columbus Zoo, unpubl. data). At the time of writing this manuscript (October 2012), the turtle is still living at the Columbus Zoo and Aquarium (Fig. 3). In 1990, the turtle was already recognized as the oldest known *M. annamensis* in

captivity (Snider and Bowler 1992, *op. cit.*). Now, at approximately 46 years old, the age of this specimen is nearly double the previously reported maximum longevity.

In addition to being the oldest documented captive individual of *M. annamensis*, this turtle, to our knowledge, is only the third specimen of the species since 1939 with reliable collection data and fills a 54-year gap in the documented presence of the species in the wild. Details on the origin of this individual have been unreported until now, leading to this specimen being overlooked in previous works. Johnson (1970, *op. cit.*), for example, documented the occurrence of 23 species of herpetofauna in Quang Nam Province based on 159 specimens collected during military operations. However, *M. annamensis* was not one of the species listed. This omission apparently occurred because Johnson left Vietnam in January 1966 (Johnson 1970, *op. cit.*), just prior to when Lowery caught the turtle.

Information on collection locality and date is generally lost when animals are obtained from the live animal trade or through confiscations from illegal poachers or traders (Fong et al. 2007. Anim. Conserv. 10:452–460). The rarity of locality-specific specimens of *M. annamensis* has hindered previous phylogenetic analysis of the species (Fong et al. 2007, *op. cit.*). As a result of her detailed provenance, this turtle potentially represents a unique opportunity in the study and recovery of this imperiled species. Genetic samples from this specimen have already been included in an ongoing project aimed at better elucidating the relationship of *M. annamensis* to other taxa and investigating any genetic structure among *M. annamensis* populations. As reintroduction efforts are currently being planned for this species (TCC 2011, *op. cit.*; McCormack, pers. comm.), such research may guide conservationists in the proper placement of individuals into the wild.

We are indebted to Jim Lowery, who kindly shared his recollections with us and permitted publishing of this information. Additional information was provided by Peter Pritchard, Jim Parham, and Bryan Stuart. Thanks to Tim McCormack and Brian Horne for their comments on an early draft of the manuscript. Special thanks to the staff and management of the Columbus Zoo and Aquarium, in particular Becky Ellsworth and Doug Warmolts, for their assistance, support, and encouragement. This paper is dedicated to the memories of the late Louis Pistoia, Mike Goode, and Mike Ewert.

SQUAMATA — LIZARDS

***OPHISAURUS ATTENUATUS ATTENUATUS* (Western Slender Glass Lizard). DEATH FEIGNING.** Death feigning (i.e., thanatosis) is a category of stationary behaviors that involves a reduction of responsiveness to external stimuli that resembles a dead or dying individual that, presumably, is used to reduce the likelihood of predation (Carpenter and Ferguson 1977. Biology of the Reptilia 7:335–554). It has been reported in a number of lizard and snake species representing many different families (e.g., Greene 1988. Biology of the Reptilia, Vol. 16:1–152). Though most observations of death feigning in lizards and snakes occur during terrestrial encounters, there have been few observations of the behavior being displayed in or on the surface of water. Within the genus *Ophisaurus*, death feigning behaviors have been reported during the handling of both *O. gracilis* (Tikader 1967. J. Bombay Nat. Hist. Soc. 65:233–234) and *O. attenuatus longicaudus* (Smith 1994. Bull. Maryland Herpetol. Soc. 30:107). Here we provide the first report of *Ophisaurus attenuatus attenuatus* death feigning in water.

On 24 June 2010, 10 individual *O. attenuatus* were captured while crossing roads in Ellis and Russell counties, Kansas, USA. These individuals were taken back to the laboratory and kept in captivity for use in an unrelated study on locomotor performance. Once in the lab, lizards were kept individually in plastic containers with commercial terrarium bedding consisting of red cypress mulch and a water dish. Lizards were fed crickets weekly and were minimally handled. On 10 August 2010, lizards were individually placed in a 2.5 m-long trough containing water (23° C) to assess their swimming abilities for the locomotor study. Though seven of the ten individuals began swimming as expected once placed in the trough, three individuals exhibited a death feigning-like behavior on the surface of the water. These three lizards weighed 18.9, 10.4, and 19.6 g and measured 31.2, 37.1, and 41.6 cm in total body length, respectively. All three lizards immediately flipped upside-down and floated motionless with their heads submerged; it was apparent that the lizards were not breathing throughout the duration of the death feign (Fig. 1). The investigator stood motionless ca. 1 m from the lizards throughout the death feign so that they could be captured at the conclusion of the behavior. All three lizards voluntarily righted themselves after an average of 246 sec (134, 342, and 262 sec) and began to quickly swim away from the investigator until they were recaptured. After several successive death feigning displays for each lizard (3-5 displays), each lizard elected to swim down the aquatic raceway rather than feign death.

Death feigning on water has been previously described in snakes of the genera *Storeria* (Gerald 2008. Anim. Behav. 75:647–654) and *Heterodon* (Gehlbach 1970. Herpetologica 26:24–34). To our knowledge, this is the first report of a lizard death feigning while floating on the water's surface. The fact that this behavior occurred with *O. attenuatus* on water is unique because slender glass lizards are considered terrestrial lizards that prefer grassland habitats (Fitch 1989. Occ. Papers Mus. Nat. Hist. Univ. Kansas 125:1–50). There are no reports, to our knowledge, of this species using or crossing any body of water. Placement of these lizards in water was likely a very stressful event that resulted in a rarely seen behavior. The lizards did surface swim very quickly (similar to that observed in snakes) when the feigning behavior ceased. As a result, their presumed lack of experience in this medium may have resulted in lizards displaying the behavior sooner than they normally would as opposed to attempting to flee first. The behaviors were not due strictly to handling prior to placement in water because the lizards did not feign death after handling or upon subsequent placement on a terrestrial surface both before and after the observed behaviors.

Many lizards have been reported to feign death prior to or as a result of handling when they feel cornered by a predator. Several studies have suggested that death feigning is advantageous as a last line of defense when the likelihood of active escape from a predator is greatly reduced (e.g., Burghardt and Greene 1988. Anim. Behav. 36:1842–1844; Gerald 2008. Anim. Behav. 75:647–654). The observation that *O. attenuatus* initially feign death in water is consistent with this hypothesis if lizards lack experience and are unsure of their locomotor abilities in water. Though this

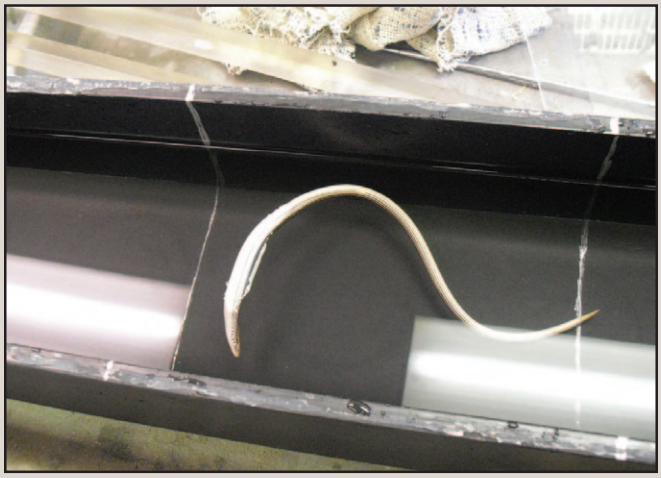

FIG. 1. Western Slender Glass Lizard (*Ophisaurus attenuatus attenuatus*) death feigning while floating on the water's surface.

may be a rare behavior in *Ophisaurus* (as well as in many other lizard species), it may be a beneficial behavior when lizards are captured or cornered by predators, or when they find themselves in unusual microhabitats or other situations as a result of actions by a potential predator.

***PHRYNOSOMA GOODEI* (Goode's Horned Lizard). AGGRESSIVE BEHAVIOR.** Behavioral reports of horned lizards are scattered (Sherbrook 2003. Introduction to Horned Lizards of North America. University of California Press, Berkeley, California. 178 pp.). There have been several reports detailing defensive behavior in *Phrynosoma* using blood-squirting (Sherbrooke and Middendorf 2001. Copeia. 2001:1114–1122), social behavior, and display patterns (Lynn 1965. Southwest. Nat. 10:25–30; Tollestrup 1981. Herpetologica 37:130–141 and references therein), but only a few references report aggressive behavior. Here, I describe aggressive behavior in *P. goodei* under laboratory conditions.

In July and August 2010, I collected 35 adult *P. goodei* in the El Pinacate and Gran Desierto de Altar Biosphere Reserve, Sonora (31.5839°N, 113.4951°W; 80 m elev.) to conduct a thermal preference study. In the laboratory, the horned lizards were separated by gender and maintained at 25°C in plastic containers with sand, trunks, and grass, fed ants, and hydrated daily with a sprinkler. Laboratory experiments were conducted two or three days after capture using a thermal gradient. The thermal gradient consisted of a wooden box 150 cm long × 100 cm wide × 70 cm high, divided into ten tracks of 10 cm each to prevent interaction between lizards. The box was located in a room with controlled temperature of 20°C and three 150-W lamps were placed at different heights over the box to offer a thermal gradient (20–50°C). I took body temperature manually using a digital thermometer in the thermal gradient each hour between 0930 and 1900 h. During the thermal experiment, three specimens (two males and a female 70, 69 and 69 mm SVL, 40, 39 and 43 mm tail length, 14.2, 14 and 14 g, respectively) exhibited aggressive behavior when I attempted to take their body temperature. After laboratory experiments, all lizards were released at the site of capture.

The aggressive display consisted of a jump forward with the lizard reaching two or three centimeters from the ground. The jump was accompanied with a hissing sound and an open mouth. In the initial position, the lizards raised the posterior portion of their body and lowered the front part of the body (i.e., placing forelimbs flexed and hindlimbs fully extended). From this posture, the lizards hopped when I tried to lift them up. The lizards displayed this behavior up to eight times in a row when I tried to approach them with my hand or another object. The hissing sound was produced only during exhalation. Before each jump the lizards swayed from side to side. These defensive behaviors likely maximize the chances of escape against certain would-be predators.

Previously, similar displays were reported in *P. douglasii*, *P. hernandesi*, *P. cornutum* (Milne and Milne 1950. Am. Midl. Nat. 44:720–741), and *P. platyrhinos* (Lowe and Woodin 1954. Herpetologica 10:48). This is the first report on such displays for *P. goodei*.

I thank Luis Rivera, Javier Verdugo, and Aníbal Díaz de la Vega for field assistance, CONANP for facilities granted during our stay, and Tereza Jezkova for comments on the manuscript.

Batrachochytrium dendrobatidis in Amphibians of the Piedmont and Blue Ridge Provinces in Northern Georgia, USA

The amphibian chytrid fungus, *Batrachochytrium dendrobatidis* (*Bd*), has been found in the state of Georgia, USA but the full extent of its distribution in that region is not well understood (Gonynor et al. 2011; Hossack et al. 2010; Timpe et al. 2008). Although previous studies in Georgia have found a low prevalence of *Bd*, more in-depth studies are needed to establish locations of *Bd* infections, provide a better assessment of infection rates, and assess the vulnerability of different species to symptoms of the disease chytridiomycosis because such species may be vulnerable to population declines in the future. Georgia is rich in amphibian biodiversity, with 87 species known to occur within the state (CNAH 2012). Conserving amphibians is important because they account for the majority of the vertebrate biomass in the area and are centrally nested in food webs, supplying higher-level predators with energy (Wright et al. 2001).

Our aim was to determine the extent of *Bd* infection in stream and stream-bank amphibians in two different physiographic provinces in Georgia, the Blue Ridge Mountains of the Southern Appalachian Mountains and the lowland Piedmont Province around the Atlanta region. This is the only multiple-site *Bd* survey of the Atlanta area. We hypothesized that *Bd* would have higher prevalence in the montane Blue Ridge province sites since previous studies have detected *Bd* in amphibians in high elevation areas possibly due to lower preferred developmental temperatures (Daszak et al. 1999; Longcore et al. 1999). Streams were chosen for sampling because species restricted to these areas may be the most prone to infection (Kriger and Hero 2007). We attempted to examine the factors that affected the occurence of *Bd* and quantify the levels between the Georgia amphibian communities within the Piedmont and Mountain provinces.

Ten sites were selected for *Bd* sampling. Five sites were located in the Blue Ridge province around Cooper Creek (Union Co., Georgia) in a Wildlife Management Area located within the Chattahoochee National Forest, and five sites were in the Piedmont Province near the city of Atlanta (Arabia Mountain Natural Heritage Area, Fernbank Forest, Lullwater Preserve, Panola Mountain State Conservation Park, Stone Mountain Park) (Fig. 1, Table 1). A site was defined as a permanent first-order stream reach (~50 m of stream length) and the near-bank area, within two meters of the stream.

Sampling was conducted from September 2010 to early December 2010 with each site being sampled approximately once a month. The same location was sampled each time. Sites were hand-sampled by flipping over rocks and down wood as well as dip netting in the water. Larvae were not sampled due to difficulty of determining species, especially among the salamanders. Each individual was swabbed for *Bd* (Brem et al. 2007) using polyester swabs. Swabs were subsequently stored in a freezer at -20°C. Once a site was sampled, all nets and shoes were disinfected with a 10% solution of bleach to prevent the spread of *Bd* from site to site. New non-powdered gloves were used when handling individuals, and each individual was kept in a new zip-loc bag to minimize the potential for cross-infection among captures.

Swab DNA extractions were conducted at Emory University. The DNA from each swab was extracted using a DNeasy Blood and Tissue kit (Qiagen). To assess *Bd* presence, we used real-time PCR (polymerase chain reaction) assays using SYBR green and an Applied Biosystems StepOnePlus Real-Time PCR System. The primers were chosen based upon those designed by Boyle et al. (2004). Reactions (10 µL) containing 5 µL of SYBR green master mix (Applied Biosystems) primers at a concentration of 5 pmol/mL and 1 µL of DNA were prepared in duplicate and used for the PCR assays. Each plate was run with pure water as a negative control and known *Bd* DNA at a concentration of 10 ng/µL as a positive control. Melting curve analysis after amplification was used to confirm that positive test samples had the same melting temperature as the positive control. Samples were run in triplicate, and if at least two of three samples matched the positive control, the sample was deemed positive for *Bd*. To quantify the amount of *Bd* in positive samples relative to a control of known *Bd* DNA concentration, each positive sample was run again, in triplicate, alongside a diluted standard series. The *Bd* DNA concentration of each positive sample was then estimated relative to these standards.

We used logistic regression to examine associations between *Bd* occurrence in individuals, province, and species. Generalized linear models using a binomial logit distribution were used for the occurrence (*Bd* present or not found) dataset, which allowed for simultaneous comparisons of multiple variables. To examine

**Corresponding author; e-mail: lwilso3@emory.edu*

the association of province with *Bd* occurrence, a subset of the data was analyzed which included those species found in both province types. To examine associations between *Bd* concentration levels within individuals and factors such as province and species, only samples that tested *Bd*-positive were analyzed. We used analysis of variance (ANOVA) to account for the continuous data (*Bd* concentrations) rather than the binomial distribution used for the categorical data used in the occurrence analyses. Since the data were not normal according to a Kolmogorov-Smirnov test, all values were log-transformed for all analyses. All statistical tests were run using JMP (SAS Institute Inc., 2010, ver. 9.0.0).

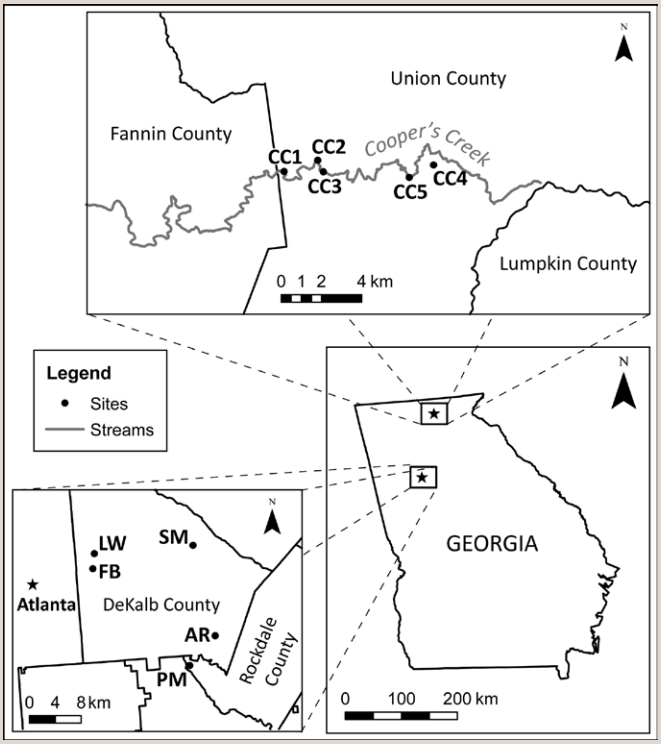

FIG. 1. Locations where amphibians were sampled for *Batrachochytrium dendrobatidis* in Georgia, USA. Ten study sites in two provinces are shown: CC 1–5 are upland sites around Cooper Creek in the Blue Ridge Mountain province of the Southern Appalachian Mountains; sites in the Piedmont Province include AR (Arabia Mountain Natural Heritage Area), FB (Fernbank Forest), LW (Lullwater Preserve), PM (Panola Mountain State Conservation Park), and SM (Stone Mountain Park).

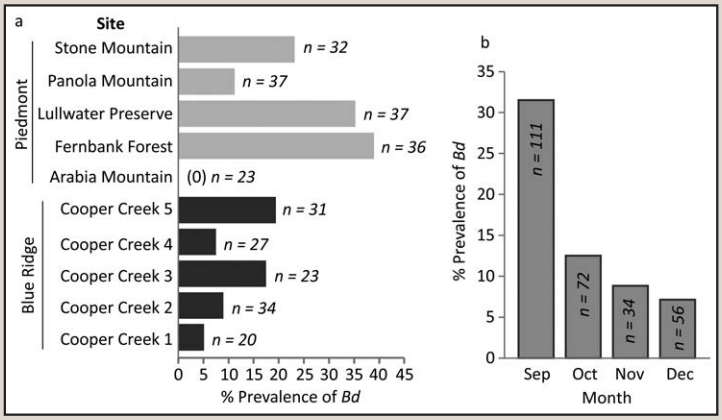

FIG. 2. A) Occurrence of *Batrachochytrium dendrobatidis* (*Bd*) infections among individual amphibians sampled at ten sites from two different provinces in northern Georgia, USA. B) *Bd* infections occurred during all months of sampling (September to December 2010) but were most prevalent during September.

A total of 273 individuals of 14 species were tested for the presence of *Bd*, of which 51 (18.7%) individuals tested positive (Table 2). The most common amphibian in our study was the Black-bellied Salamander (*Desmognathus quadramaculatus*; 57 captures in the Blue Ridge province) and the most common anuran was the Northern Cricket Frog (*Acris crepitans;* 23 captures in the Piedmont province). Four species were caught in both provinces: North American Bullfrogs (*Lithobates catesbeianus*), Seal Salamanders (*Desmognathus monticola*), Red Salamanders (*Pseudotriton ruber*), and Spring Salamanders (*Gyrinophilus porphyriticus*). The species with the highest *Bd*-occurrence rate (80%) was the North American Bullfrog, but our sample size was small for this species (N = 5). Our sample size for several other taxa also was low, reducing our confidence in the accuracy of *Bd* occurrences. Skerratt et al. (2008) recommended a sample > 59 in order to effectively detect *Bd* occurrence in populations with a low infection rate. The second-most infected species in our sample was the Southern Two-lined Salamander (*Eurycea cirrigera*; 57.4%; N = 47 individuals sampled). However, the individual that was host to the greatest quantity of *Bd* was a Seepage Salamander (*Desmognathus aeneus*; 99.1 ng/µL). Most individuals had less than 1 ng/µL of *Bd*. The sites with the highest occurrence of *Bd* infection were Fernbank Forest (38.9%, N = 36) and Lullwater Preserve (35.1%, N = 37), both of which were in the Piedmont Province. The only site that had no occurrence of *Bd* was Arabia Mountain, also within the Piedmont and no symptoms of *Bd* were seen at this location throughout the study.

Within our study there appears to be an effect of province on *Bd* occurrence when considering all species together, with more infected individuals found in the lowland Piedmont area (Fig. 2A). However, to adequately address this statistically, to separate province and species effects, we analyzed a subset of the data to include only those species caught in both provinces. This analysis revealed no statistical effect of province or species on the occurrence of *Bd*; therefore, province was excluded from all subsequent analyses of occurrence. However, for the entire data set, species was a significant factor associated with *Bd* occurrence ($\chi^2 = 71.8166$, df = 14, $p < 0.0001$). Additionally, there appeared to be a seasonal decline in *Bd* occurrence in the fall, with more infections occurring in September (Fig. 2B), but this trend was only significant for some species (e.g., *D. ocoee* and *E. cirrigera*, $\chi^2 = 14.00$, df = 1, N = 30, $p = 0.0002$, $\chi^2 = 12.53$, df = 1, N = 47, $p = 0.0004$).

Neither province nor time of year influenced the severity of infection within individuals (province, one-way ANOVA, $F(1,49) = 2.63$, $p = 0.11$, month, one-way ANOVA, $F(3, 47) = 1.08$, $p = 0.37$). Species, on the other hand, significantly affected the amount of *Bd* on an individual (one-way ANOVA, $F(6, 44) = 3.17$, $p = 0.011$) (Table 2). However, this significance is due to an outlier of a single *D. aeneus* (99.09 ng/µL) that had over seven times as much *Bd* as the next highest individual, which was *L. catesbeianus* (12.84 ng/µL). Upon removal of this *D. aeneus* individual, species was no longer significant (one-way ANOVA, $F(6, 43) = 2.10$, $p = 0.073$).

Our data do not support our hypothesis that there would be a higher occurrence of *Bd* in the cooler mountains.

Although we found *Bd* infections in both the mountains and lowland areas, there was a greater prevalence of infection in both the warmer lowlands as well as the warmer months within the timeframe examined. The U.S. National Weather Service data show that the mountain sites in Union County, Georgia are cooler than the Piedmont sites. The average high temperature is 2°C less, the average low is 5°C less and the mountain sites receive on average 159 mm more precipitation (The Weather Channel 2011). These findings were initially surprising since previous studies showed lower prevalence of *Bd* infections in lowland areas (Berger et al. 1998). However, predictions based upon earlier research in the tropical habitats of Central America and northern Australia may be inappropriate for the more temperate climate of Georgia, USA. In particular, our lowland fall season surveys were conducted during temperature regimes suitable for *Bd*. The average temperature for the Piedmont Province area at the start of the survey in September is 23°C (The Weather Channel 2011), very close to the ideal temperature for the development of *Bd*. This would explain why the highest prevalence of *Bd* infection was found during this month. After September, as the months became colder (average temperatures of 17.5°C, 12.5°C, and 7.5°C for October, November, and December, respectively) (The Weather Channel 2011) the number of infections decreased (Fig. 2B), potentially due to lower temperatures being less suitable for *Bd* growth.

In our study, the specific reason for why one species might be more likely to be infected is unclear. It is possible that there is a life history strategy difference or some other behavioral cause for differences in likelihood of infection between species (Bancroft et al. 2011; Searle et al. 2011). For example, many amphibians are known to perform behaviors such as grouping to overwinter or aggregate for breeding, both of which could increase the likelihood of transmitting *Bd* (Myers and Zamudio 2004; Ultsch et al. 2000). Continued monitoring of these species is warranted in order to establish if any species may be at risk for development of chytridiomycosis and potentially suffer mortality rates that may lead to a population decline. Lastly, the increase of *Bd* infections since the previous survey in Georgia in 2008, which found a 1.88% prevalence (Timpe et al. 2008), is of interest. However, the spatial and temporal scopes of sampling and species sampled differed among our two studies making them difficult to compare. Nevertheless, this possible trend toward greater infection rates in Georgia is another reason to establish a monitoring program of both *Bd* and amphibian populations in this region.

Acknowledgments.—We thank R. Hill from the Atlanta Botanical Gardens and ZooAtlanta for helping design the sampling protocol as well as supplying many materials. In addition, without the invaluable help of E. Huang, G. Manser, L. Neilson, D. Wilson, as well as T. Madden and C. Showalter from Fernbank Science Center, the sample size would be considerably smaller. We also thank M. Yabsley and his staff in Southeastern Cooperative Wildlife Disease Study at University of Georgia Athens for assistance with *Bd* sampling and analysis, and J. Kovacs for statistical assistance. Lastly, the project could not have happened without the help of N. Gerardo and D. Sok in providing a space to run DNA extractions and real-time PCR. Research was

Batrachochytrium dendrobatidis Not Detected in Anurans in the Northern Kimberley Region of Western Australia

Chytridiomycosis, caused by the fungal pathogen *Batrachochytrium dendrobatidis* (*Bd*), is recognized as a significant threat to amphibian populations worldwide (Skerratt et al. 2007). The distribution and virulence of *Bd* appears to be dependent on various host and environmental parameters including host species, habitat, precipitation and temperature (Murray et al. 2011a; Puschendorf et al. 2011). The likelihood of *Bd* occurring in the range of bioregions across Australia is predicted in the model proposed by Murray et al. (2011b). The model predicts that chytridiomycosis is unlikely to occur in arid and hot regions such as in northwestern Australia. However, sampling in these regions has been scant (Murray et al. 2010, 2011b). Most opportunistic reports and systematic surveys of *Bd* in Australia have been limited to the eastern, south-eastern and south-western coastal regions where overt population effects have been reported (Murray et al. 2010, 2011b). Therefore, we examine the predictions of Murray et al. (2011b) by opportunistically screening frogs for *Bd* as part of a biodiversity survey of vertebrate fauna in the north Kimberley region of north Western Australia.

We sampled 14 locations across Doongan and Theda Stations from 3–27 May 2011 (Table 1, Fig. 1). In this area of the arid Kimberley region, mean maximum air temperatures are lowest from May to July, ranging from 29.0°C to 31.1°C (Australian Government Bureau of Meteorology 2012); hence, this is the most favorable time of year for the detection of *Bd* (Berger et al. 2004). Each location included 7–8 survey sites (62 sites, total), representing a range of different habitat types (and proximity to water) within the sampled landscape. The landscape sampled was dominated by savannah woodland or open woodland (*Eucalyptus tetradonta*, *E. tectifica*), and included grassland (hummock and tussock), shrubland, forest, rainforest, and paperbark swamps. At each site, four pitfall traps and eight terrestrial funnel traps

were checked each morning for four consecutive nights. Additionally, 60 minutes diurnal and 20 minutes nocturnal searching was conducted at each site, during which time frogs were hand caught opportunistically.

All amphibians captured were adult frogs, and were handled using clean plastic bags. The skin of each frog was thoroughly swabbed (Medical Wire & Equipment Co [UK] MW 100-100 sourced from Biomerieux Australia), with emphasis given to the ventral abdomen, thighs, and feet. Frogs were released at the capture site on the same day. Frogs were not marked for identification; it is unknown if individuals were caught and sampled on more than one occasion. Swabs were refrigerated at 4–8°C until processing. Swabs were tested in taxonomically-based batches of three for *Bd* DNA using the real time quantitative PCR test described by Boyle et al. (2004) with modifications proposed by Hyatt et al. (2007) and Garland et al. (2010). This modified PCR test has been validated for wild amphibians (Skerratt et al. 2011).

Swabs were collected from 287 anurans representing seven genera and 16 species (Table 2). All samples tested negative for *Bd* DNA. All live frogs sampled appeared healthy. Nine *Uperoleia* sp. and one *Litoria inermis* were found dead in funnel traps, predominantly clustered over two consecutive nights; these deaths were attributed to dehydration due to inappropriate microclimate in the traps, and were not investigated further.

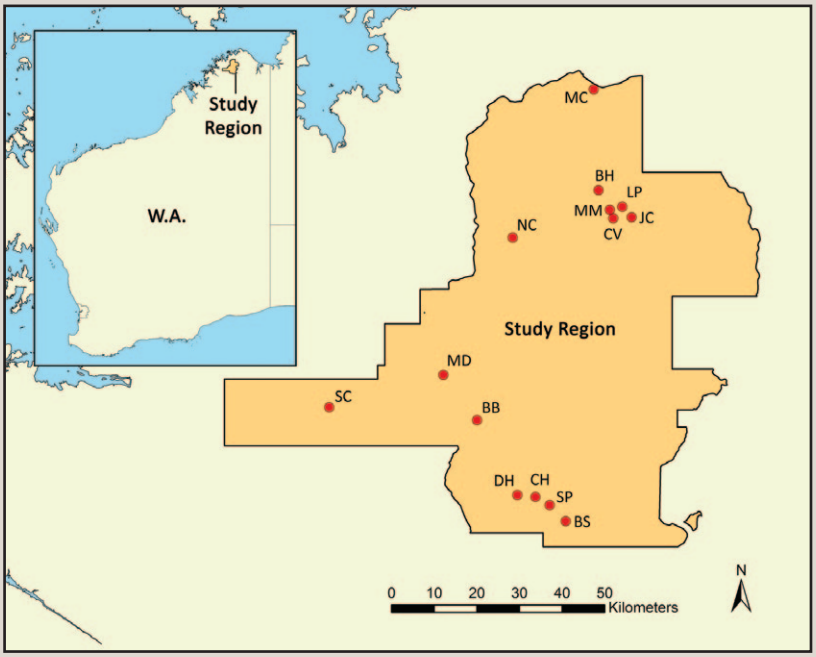

FIG. 1. Sampling locations for *Batrachochytrium dendrobatidis* within the study region in the north Kimberley, Western Australia (site codes correspond to Table 1).

FIG. 2. *Limnodynastes convexiusculus*, north Kimberley, Western Australia.

Our inability to detect *Bd* in this population is consistent with the model proposed by Murray et al. (2011b). The climate and ecology of the surveyed region is likely inappropriate to support *Bd*. Mean monthly maximum air temperatures are consistently >29°C, which are likely correlated to water temperatures. Temperatures >27°C are known to be unfavorable for chytridiomycosis (Berger et al. 2004). However, it is conceivable that *Bd* could occur in pockets of favorable aquatic microclimates within the Kimberley region. Rainfall is markedly seasonal; monthly averages range from 0.4 mm in June to >300 mm in January. Higher rainfall favors *Bd* (Skerratt et al. 2008). The low winter rainfall in the northern Kimberley would likely limit *Bd* to permanent water bodies; high summer rainfall coincides with mean monthly maximum air temperatures >32°C which may raise water temperatures above the tolerance threshold for *Bd*.

Skerratt et al. (2008) suggested a sample size of 60 to give at least 95% confidence of detecting at least one positive individual, assuming a minimum apparent prevalence of 5%. This sampling protocol has been shown to detect *Bd* where it is known to occur in Queensland (Skerratt et al. 2010). However, if *Bd* occurs in the Kimberley region at lower levels than elsewhere in Australia, then inadequate sampling may explain our inability to detect *Bd*. At the species level, we achieved a sample size >60 only for *Limnodynastes convexiusculus* (Fig. 2) and *Uperoleia* spp. (the extent of local species diversity in the latter genus is yet to be resolved), the predominant species captured. It is likely that these species are relatively abundant in this bioregion, or at least that capture methods biased the diversity of species sampled. Murray and Skerratt (2012) predicted the probability of infection in *L. convexiusculus* as unlikely at 0.3, and slightly higher in a number of untested *Uperoleia* spp. at 0.5–0.6. This is because they largely occur in regions climatically less favorable for *Bd* and are ephemeral breeders. However, other species belonging to both these genera and ecological groups have tested positive in areas favorable for chytridiomycosis (Murray et al. 2010).

The presence of *Bd* cannot be ruled out altogether if it is overdispersed in amphibian species (i.e., it occurs in few species), or in areas within this region such as in favorable microclimates, as may occur in Arizona, USA (Bradley et al. 2002). However, this has generally not been found to occur in other regions of northern Australia (Skerratt et al. 2010). It is also possible that *Bd* has not had an opportunity to disperse to this area; it has managed to achieve long distance dispersal across ecological barriers within Australia, such as across Bass Strait to Tasmania, and across the arid Nullarbor Plain to southern Western Australia, possibly through movement of infected amphibians (Murray et al. 2010).

Acknowledgments.—We acknowledge David Taggart, Wendy Foster, staff at Conservation Ark / Zoos South Australia, the ecologists

GEOGRAPHIC DISTRIBUTION

Herpetological Review publishes brief notices of new geographic distribution records in order to make them available to the herpetological community in published form. Geographic distribution records are important to biologists in that they allow for a more precise determination of a species' range, and thereby permit a more significant interpretation of its biology.

These geographic distribution records will be accepted in a **standard format** only, and all authors *must* adhere to that format, as follows: SCIENTIFIC NAME, STANDARD ENGLISH NAME if available (for the United States and Canada as it appears in Crother [ed.] 2012. *Scientific and Standard English Names of Amphibians and Reptiles of North America North of Mexico, with Comments Regarding Confidence in Our Understanding*. 7th ed. Herpetol. Circ. 39:1–92 [available from ssarbooks.com], for Mexico as it appears in Liner and Casas-Andreu 2008. *Standard Spanish, English and Scientific Names of the Amphibians and Reptiles of Mexico*. Herpetol. Circ. 38:1–162), LOCALITY (use metric for distances and give precise locality data, including lat/long coordinates in **decimal degrees** and cite the map datum used), DATE (day-month-year), COLLECTOR, VERIFIED BY (*cannot* be verified by an author; curator at an institutional collection is preferred), PLACE OF DEPOSITION (where applicable, use standardized collection designations as they appear in Sabaj Pérez [ed.]. 2010, *Standard Symbolic Codes for Institutional Resource Collections in Herpetology and Ichthyology: an Online Reference*, ver. 2.0, available at http://www.asih.org/) and CATALOG NUMBER (required), COMMENTS (brief), CITATIONS (brief and must adhere to format used in this section; these should provide a geographic context for the new record). Close with author name(s) in bold, capital letters (give name and address in full—spell out state or province names—no abbreviations, e-mail address after each author name/address for those wishing to provide it—e-mail required for corresponding author). Please include distance from nearest previously known record (provide a citation or refer to existing vouchered material to substantiate your report). If publishing specific locality information for a rare or endangered species has the potential to jeopardize that population, please consult with the Section Editor at time of record submission. If field work and/or specimen collection occurred where permits were required, please include permit number(s) and authorizing agency in the text of the note.

Some further comments. The role of the "Standard Names" lists (noted above) is to standardize English names and comment on the current scientific names. Scientific names are hypotheses (or at least represent them) and as such their usage should not be dictated by a list, society, or journal.

Additionally, this geographic distribution section does not publish "observation" records. Records submitted should be based on preserved specimens that have been placed in a university or museum collection (private collection depository records are discouraged; institutional collection records will receive precedence in case of conflict). A good quality photograph (print, slide, or digital file) may substitute for a preserved specimen *only* when the live specimen could not be collected for the following reasons: it was a protected species, it was found in a protected area, the observer lacked the necessary permit for collection, or the logistics of preservation were prohibitive (such as large turtles or crocodilians). Photographic vouchers *must* be deposited in a university or museum collection along with complete locality data, and the photographic catalog number(s) must be included in the same manner as a preserved record. Before you submit a manuscript to us, check Censky (1988, *Index to Geographic Distribution Records in Herpetological Review: 1967–1986*; available from the SSAR Publications Secretary), subsequent issues of *Herpetological Review*, and other sources to make sure you are not duplicating a previously published record. The responsibility for checking literature for previously documented range extensions lies with authors. **Do not submit range extensions unless a thorough literature review has been completed.**

Please submit any geographic distribution records in the **standard format only** to one of the Section Co-editors: **David C. Blackburn** (Africa and Europe), **Indraneil Das** (Asia, Australasia), **Jerry D. Johnson** (Mexico and Central America, including the Caribbean Basin), **Alan M. Richmond** (USA & Canada), or **Gustavo J. Scrocchi** (South America). Short manuscripts are discouraged, and are only acceptable when data cannot be presented adequately in the standard format. **Electronic submission of manuscripts is required** (as Microsoft Word or Rich Text format [rtf] files, as e-mail attachments)**.** Refer to inside front cover for e-mail addresses of section editors.

Recommended citation for new distribution records appearing in this section is: Cabral, H., and A. Caballero. 2012. Geographic distribution: Paraguay, Departamento Central: *Pseudoeryx plicatilis*. Herpetol. Rev. 43:622.

CAUDATA — SALAMANDERS

***AMBYSTOMA OPACUM* (Marbled Salamander)**. USA: MISSOURI: Madison Co.: Fredericktown. Found in wooded area near fishless pond located 50 m E of Piney Creek (37.5625°N, 90.413056°W; WGS84). 1 September 2012. Abbigail E. Nicholson. Verified by Dustin S. Siegel. University of Missouri-Columbia (UMC 2197P). New county record. This record fills the gap among surrounding Bollinger, Iron, St. Francois, and Wayne counties (Edmond and Daniel 2012 [latest update 13 April 2012]. Missouri Herpetological Atlas Project. Available at http://atlas.moherp.org/; accessed 17 October 2012).

***ELEUTHERODACTYLUS PLANIROSTRIS* (Greenhouse Frog).** USA: GEORGIA: Tift Co.: Tifton (31.480529°N, 83.507719°W; WGS 84). 27 October 2012. Todd Pierson and Malavika Rajeev. Verified by Kenneth Krysko. Florida Museum of Natural History (UF 169095 photo voucher). New county record (Jensen et al. 2008. Amphibians and Reptiles of Georgia. University of Georgia Press, Athens. 575 pp.). This non-native frog has been recorded in scattered counties throughout southern Georgia. We uncovered seven adults across a suburban backyard.

TODD PIERSON (e-mail: twpierso@uga.edu) and **MALAVIKA RAJEEV** (e-mail: mrajeev@uga.edu), Odum School of Ecology, University of Georgia, Athens, Georgia 30609, USA.

***HYLA CINEREA* (Green Treefrog).** USA: INDIANA: Warrick Co.: Old Channel Cut-off, Cypress Creek, Anderson Township (37.936805°N, 87.347805°W; WGS 84) 20 June 2012. Michael J. Lodato. Verified by Chris Phillips. Illinois Natural History Survey (INHS 2012k). New county record (Lodato et al. 2004. Herpetol. Rev. 35[3]:281; Minton 2001. Amphibians and Reptiles of Indiana, 2nd ed., revised. Indiana Academy of Science. vii + 404 pp.). Specimen collected from vegetation at margin of wetland. Chorusing males first noted at this site in May 2005 and a breeding colony has been established there since that time. This collection represents the third known county record for *H. cinerea* in Indiana, a species new to the state since 2003.

MICHAEL J. LODATO, 925 Park Plaza Drive, Evansville, Indiana 47715, USA; e-mail: mikelodato@wowway.com.

***INCILIUS CAMPBELLI* (Campbell's Forest Toad).** MÉXICO: CHIAPAS: Municipality of Marquez De Comillas: Playón de la Gloria (16.142787 °N, 90.891155 °W; WGS84), 224 m elev. 12 July 2012. M. Bénard-Valle. Playón de la Gloria (16.142405 °N, 90.891833 °W; WGS84), elev. 197 m. 30 September 2012. R. Percino-Daniel and Y. García. Both verified by Antonio Muñoz-Alonso. Colección Herpetológica, El Colegio de la Frontera Sur (ECO-SCH 2549 and 2550, respectively). First accurate records for Mexico, expanding the species range ca. 32 km N of the nearest known locality in Guatemala (Mendelson 1994. Occ. Pap. Mus. Nat. Hist. Univ. Kansas 166:1–21). The two toads, along with others of both sexes from each locality, were found on leaf litter in tropical rain forest between 1200 and 1400 h. Mendelson (1997. Herpetologica 53:14–30), without comment or description, referred several specimens from NW Chiapas (TCWC 21483–85) and adjacent Veracruz (KU 27466) to *I. campbelli*. Recent re-examination of those specimens by JRM verified that they in fact represented *I. macrocristatus*.

We thank Adrian Sarabia Rangel for assistance. Fieldwork was funded by Yaxal-Na.

***LITHOBATES AREOLATUS* (Crawfish Frog).** USA: INDIANA: Spencer Co.: Hammond Township, on State Route 70, 2.5 km E intersection US Route 231 (38.002117°N, 86.996633°W; WGS 84) 26 March 2008. Michael J. Lodato. Verified by Chris Phillips. Illinois Natural History Survey (INHS 2011n). First voucher from county (Minton 2001. Amphibians and Reptiles of Indiana, 2nd ed., revised. Indiana Academy of Science. vii + 404 pp.). Specimen found alive on road during night rain.

A colony of *L. areolatus* has been known from Spencer Co. since 1998, from a site about 4 km NNE Newtonville (38.0303°N, 86.920117°W; WGS 84) and about 6 km ENE of the location cited above. This population, discovered by DSD, has been monitored each year during the breeding season but landowner restrictions have prohibited collection of vouchers from the site.

MICHAEL J. LODATO, 925 Park Plaza Drive, Evansville, Indiana 47715, USA (e-mail: mikelodato@wowway.com); **DAVID S. DUGAS**, 5029 N. County Road 150W, Chrisney, Indiana 47611, USA (e-mail: dszjdugas@psci.net).

***LITHOBATES CATESBEIANUS* (American Bullfrog).** USA: NEBRASKA: Franklin Co.: 40.002974°N, 98.902216°W (WGS 84), elev. 633 m. 24 September 2012. Brian Hubbs. Verified by Neftali

Camacho. Natural History Museum of Los Angeles County, LACM PC 1612. New county record (Ballinger et al. 2010. Amphibians and Reptiles of Nebraska. Rusty Lizard Press, Oro Valley, Arizona. 400 pp.; Fogell 2010. A Field Guide to the Amphibians and Reptiles of Nebraska. Institute of Agriculture and Natural Resources, University of Nebraska-Lincoln. 158 pp.).

BRIAN HUBBS, PO Box 26407, Tempe, Arizona 85285, USA; e-mail: tricolorbrian@hotmail.com.

***LITHOBATES CATESBEIANUS* (American Bullfrog)**. MÉXICO: COAHUILA: Municipality of Guerrero: Rancho La Burra, km 92 on Nuevo Laredo–Piedras Negras Hwy (28.0605000°N, 100.16016°W; WGS84), 200 m elev. 25 April 2010. Daniel Garza-Tobón and Julio A. Lemos-Epinal. Verified by Hobart M. Smith. Laboratorio de Ecología – Unidad de Biotechnología y Prototipos, FES-Iztacala UNAM, Tlalnepantla, México (LEUBIPRO photo voucher 2). First record for Coahuila in over 175 years (Smith et al. 2003. Newsl. Bull. Int. Soc. Hist. Bibl. Herpetol. 4:19–30; Lemos-Espinal and Smith 2007. Amphibians and Reptiles of the State of Coahuila. UNAM, CONABIO, México D.F., México. i–xiv + 550 pp). This record is about 11 km S from the Mexican border with Texas, USA. Even though the species is known from adjacent areas within the state of Texas, whether those populations are native is questionable because of rampant introduction of this species as a food resource (Dixon 2000. Amphibians and Reptiles of Texas. Texas A&M Univ. Press, College Station, Texas. i–vii + 421 pp.). However, because it was supposedly collected by Berlandier sometime between 1827 and 1834 near Saltillo, Coahuila (Lemos-Espinal and Smith 2007, *op. cit.*), there is the possibility that Rancho La Burra frogs occur within a historically naturally occurring population. The frog was found in a small (ca. 20 x 80 m) man-made reservoir.

DANIEL GARZA-TOBÓN, Fotografía y Edición de Libros de Naturaleza, Blvd. V. Carranza 4120-7, Europlaza Mall, Saltillo, Coahuila, México (e-mail: danielgarzat@prodigy.net.mx); **JULIO A. LEMOS-ESPINAL**, Unidad de Biotecnología y Prototipos, FES-Iztacala, UNAM, Av. De los Barrios No. 1, Los Reyes Iztacala, Tlalnepantla, México, CP 54090 (e-mail: lemos@unam.mx).

***PHRYNOBATRACHUS RUTHBEATAE* (Ruth-Beate's Puddle Frog)**. GABON: HAUT OGOOÉ PROVINCE: Batéké Plateau National Park, Osséré (2.0807°S, 14.0637°E; 414 m elev.) and Camp Ntsa (1.9816°S, 14.0011°E; 395 m elev.). 30 May–2 June 2011. B. M. Zimkus, J. G. Larson. Museum of Comparative Zoology (MCZ A-147865–67, 14770–73, 147882–86, 147888–91). Verified by José Rosado. This recently described species was previously known only from the type locality near Dja Biosphere Reserve in southern Cameroon where it was collected in primary swampy evergreen rainforest at 659 m elev. (Rödel et al. 2012. Zootaxa 43[1]:99). This represents the first confirmed country record in Gabon, extending the range approximately 600 km SE from the holotype locality. This species is believed to be more widespread within lowland forests of Cameroon and Gabon, including the Moukalaba-Dougoua Faunal Reserve in southwestern Gabon (*Phrynobatrachus* sp. 2; Burger et al. 2004. *In* B. L. Fisher [ed.], Monts Doudou, Gabon: a Floral and Faunal Inventory with Reference to Elevational Variation, pp. 145–186. California Academy of Sciences Memoir 28. 295 pp.). The presence of *P. ruthbeateae* within gallery forests of the Batéké Plateau National Park in southwestern Gabon makes it highly likely that this species is also distributed across the border within the Republic of Congo.

BREDA M. ZIMKUS and **JOANNA G. LARSON**, Museum of Comparative Zoology, Harvard University, 26 Oxford Street, Cambridge, Massachusetts 02138, USA (e-mail: bzimkus@oeb.harvard.edu).

***PSEUDOPALUDICOLA CANGA*.** BRAZIL: PARÁ: Municipality of Brasil Novo: 3.376°S, 52.576°W (datum WGS 84). 10 February 2012. E. A. Oliveira, J. C. Carvalho, and E. J. Hernández-Ruz. Museu Paraense Emilio Goeldi, Belém, Pará, Brazil (MPEG 34545–34553, MPEG 34584). Verified by M. S. Hoogmoed. Previously known only from the type locality: Serra dos Carajás, municipality of Marabá, State of Pará, Brazil (Giaretta and Kokubum 2003. Zootaxa 383:1–8). Northwesternmost record for the species extends known distribution 260 km NW from Serra dos Carajás, the closest locality previously mentioned.

TESTUDINES — TURTLES

***APALONE SPINIFERA* (Spiny Softshell)**. MÉXICO: SONORA: Municipio de Cananea : on a dirt road crossing of the Río San Rafael, a major tributary to the Río San Pedro, 24.8 km NNE Cananea (31.17187°N, 110.26603°W; WGS84), 1415 m elev. 6 July 2009. James C. Rorabaugh and Abigail D. King. UAZ 57185-PSV. Verified by G. Bradley. First record for Cananea, which represents the third verified record from Sonora, extending its range 449 km ESE of the nearest locality at the inflow of the Wellton Canal to the Ciénega de Santa Clara, ca. 46 km SSW San Luis Río Colorado (Rorabaugh et al. 2008. Herpetol. Rev. 39:365). The nearest record to the San Rafael locality, is ca. 21 km NNE at the San Pedro River, Arizona, USA (Corman 1988. Abundance, Distribution, and Habitat Management of the Reptiles and Amphibians of the San Pedro Riparian National Conservation Area. U.S. Bureau of Land Management, Fairbank, Arizona). This introduced species likely colonized the Río San Rafael from the Río San Pedro. The turtle was found AOR during the day in an area surrounded by plains grassland.

JAMES C. RORABAUGH, P.O. Box 31, Saint David, Arizona 85630, USA (e-mail: jrorabaugh@hotmail.com); **ABIGAIL D. KING**, Arizona Game and Fish Department, 5000 W. Carefree Highway, Phoenix, Arizona 85086, USA (e-mail: aking@azgfd.gov).

***APALONE SPINIFERA* (Spiny Softshell)**. USA: KANSAS: Coffey Co.: John Redmond Reservoir spillway (38.241370°N, 95.755066°W; WGS 84). 29 June 2012. Andrew W. Coleman and Greg Sievert. Verified by Curtis J. Schmidt. Sternberg Museum of Natural History, Fort Hays State University (FHSM 16451). New county record (Collins 2010. Amphibians, Reptiles, and Turtles in Kansas. Sternberg Museum of Natural History, Fort Hays State University, Hays, Kansas. 312 pp.). Fills a gap in the known range of this species within the Neosho River basin in eastern Kansas. A single adult turtle was found, decapitated and desiccated, on the exposed rocks within the river channel immediately below the dam on John Redmond Reservoir. The area is commonly used by anglers, one of whom presumably caught this individual accidentally.

This specimen was collected under a Kansas Wildlife Collecting Permit (SC-094-2012).

ANDREW W. COLEMAN (e-mail: acolema1@emporia.edu) and **GREG SIEVERT**, Department of Biological Sciences, Emporia State University, Emporia, Kansas 66801, USA (e-mail: gsievert@emporia.edu).

***APALONE SPINIFERA* (Spiny Softshell)**. USA: TENNESSEE: Lawrence Co.: Shoal Creek, 50 m downstream from US Highway 227 bridge (35.023681°N, 87.579013°W; WGS 84). 15 September 2012. Michael C. Fulbright, Kristen M. Pilcher, James P. Flaherty, and Chris Gienger. Verified by A. Floyd Scott. Austin Peay State University Museum of Zoology (APSU 19359 [color photo]). New county record (Scott and Redmond 2008 [latest update 7 August 2012]. Atlas of Reptiles in Tennessee. The Center for Field Biology, Austin Peay State University, Clarksville, Tennessee. Available at http://apsu.edu/reptatlas/, accessed 17 September 2012). Juvenile hand captured in backwater.

MICHAEL C. FULBRIGHT (e-mail: mfulbright@my.apsu.edu), **KRISTEN M. PILCHER**, **JAMES P. FLAHERTY**, and **C. M. GIENGER**, Center of Excellence for Field Biology, Austin Peay State University, Clarksville, Tennessee 37044, USA.

***APALONE SPINIFERA EMORYI* (Texas Spiny Softshell)**. USA: CALIFORNIA: Orange Co.: Yorba Linda (33.85704°N, 117.79071°W, WGS84; elev. 87 m). 16 September 2012. Daniel Jablonski. Verified by Gregory B. Pauly and Neftali Camacho. LACM PC 1608–1611. New county record (Lemm 2006. Field Guide to Amphibians and Reptiles of the San Diego Region. University of California Press, Berkeley. 326 pp.; Somma 2012. USGS Nonindigenous Aquatic Species Database. Available online at <http://nas.er.usgs.gov/queries/FactSheet.aspx?speciesID=1275>; Stebbins and McGinnis 2012. Field Guide to Amphibians and Reptiles of California. University of California Press, Berkeley. 538 pp.). One subadult specimen (~180 mm SCL) was discovered in the bank areas of the Santa Ana River (water depth approx. 200 mm) in urban area of Yorba Linda (southern outskirt of the city). The closest record to the Yorba Linda specimen was found in El Dorado Park, Long Beach, Los Angeles Co. (Somma, *op. cit.)*.

This introduced species has been previously observed in California in Contra Costa, Los Angeles, Kern, San Diego, and Santa Clara counties and in the Sacramento River system (Stebbins and McGinnis, *op. cit.*; Somma, *op. cit.*).

DANIEL JABLONSKI, Department of Zoology, Faculty of Natural Sciences, Comenius University, Mlynská dolina B-1, 842 15, Bratislava, Slovakia; e-mail: daniel.jablonski@balcanica.cz.

***APALONE SPINIFERA GUADELUPENSIS* (Guadalupe Spiny Softshell)**. USA: TEXAS: Liveoak Co.: northeast of the town of Three Rivers (28.502675°N, 98.077247°W; WGS84). 11 May 2009. Eric C. Munscher and Mick Cook. Verified by Carl J. Franklin (UTADC 7626–7629 photo voucher). New county record (Dixon 2000. Amphibians and Reptiles of Texas. Texas A&M University Press, College Station. 421 pp.). Two adult (one female and one male) turtles were captured in double-throated hoop nets. This species is documented in the surrounding counties of McMullen, Duval, San Patricio, Karnes, and Atascosa (Dixon 2000, *op. cit.*).

ERIC C. MUNSCHER (e-mail: emunscher@swca.com) and **MIKE COOK** (e-mail: mcook@swca.com), SWCA Environmental Consultants, Houston, Texas 77040, USA.

***CHELYDRA SERPENTINA* (Snapping Turtle)**. USA: FLORIDA: Suwannee Co.: E Peacock Springs (30.12218°N, 83.13221°W; WGS84). 3 November 2012 . Eric C. Munscher, David H. Rogers, Stephen G. Ross, and Charles Huang. Verified by Kenneth Krysko. Florida Museum of Natural History (UF 168690 photo voucher). New county record (Krysko et al. 2011. Atlas of Amphibians and Reptiles in Florida. Final report, Florida Fish and Wildlife Conservation Commission, Tallahassee. 524 pp.).

An adult male (carapace length 389 mm, midline plastron length 273 mm, 12.5 kg) was captured by hand as we snorkeled on 3 November 2012 as a part of a long-term turtle population study at Peacock Springs State Park. This species has been documented in the surrounding counties of Columbia, Gilchrist, Layfette, Madison, and Hamilton. Peacock Springs State Park is located just north of the Suwannee River and at times of high water is hydrologically connected to the river. It is possible that this species is abundant within the county but has been overlooked.

WAGNER**, Department of Natural Resource Management, South Dakota State University, Brookings, South Dakota 57007, USA (e-mail: matthew.wagner@sdstate.edu).

***CHELYDRA SERPENTINA* (Snapping Turtle)**. USA: TEXAS: Comal Co.: New Braunfels, Landa Park (29.713446°N, 98.135651°W; WGS84). 14 April 2012. Eric C. Munscher and Stephen G. Ross. Verified by Carl J. Franklin (UTADC 7618, 7622, photo vouchers) New county record (Dixon 2000. Amphibians and Reptiles of Texas. Texas A&M University Press, College Station. 421 pp.). This species has been documented in the surrounding counties of Kendall, Blanco, Hays, and Caldwell. Two adult turtles (male, female) were captured in a double-throated hoop net. Four additional turtles (three females, one male) have also been caught (UTADC 7623–7629).

Studies conducted under permit # SPR-0212-019.

ERIC C. MUNSCHER (e-mail: emunscher@swca.com) and **STEPHEN G. ROSS**, SWCA Environmental Consultants, Houston, Texas 77040, USA (e-mail: sross@swca.com).

***CHRYSEMYS PICTA BELLI* (Western Painted Turtle)**. USA: NEBRASKA: Franklin Co.: 40.098211°N, 98.780119°W (WGS 84); elev. 554 m. 24 September 2012. Natural History Museum of Los Angeles County (LACM PC 1613). Gosper Co.: 40.669192°N, 99.859899°W (WGS 84), elev. 770 m. 17 September 2012. Hall Co.: Grand Island (40.887326°N, 98.353157°W, WGS 84; elev. 568 m). 22 September 2012.

All specimens were observed by Brian Hubbs and are new county records (Ballinger et al. 2010. Amphibians and Reptiles of Nebraska. Rusty Lizard Press, Oro Valley, Arizona. 400 pp.; Fogell 2010. A Field Guide to the Amphibians and Reptiles of Nebraska. Institute of Agriculture and Natural Resources, University of Nebraska-Lincoln. 158 pp.). All specimens were verified by Neftali Camacho.

BRIAN HUBBS, P.O. Box 26407, Tempe, Arizona 85285, USA; e-mail: tricolorbrian@hotmail.com.

***DEIROCHELYS RETICULARIA* (Chicken Turtle)**. USA: ALABAMA: Covington Co.: County Rd. 24 (31.10239°N 86.43944°W; WGS 84). 17 July 2012. J. Newman, G. Brooks, and C. Thawley. Verified by David Laurencio. AUM AHAP-D 597 (digital photograph file). New county record (Mount 1975. The Reptiles and Amphibians of Alabama. Auburn Printing Co., Auburn, Alabama. 270 pp.). This record fills a distributional gap along the southern edge of the state of Alabama between Escambia and Geneva counties. The closest record in Escambia Co. is approximately 20 miles west of this record, and the closest record in Geneva Co. is approximately 20 miles to the east.

Funding for this research was provided by IOS-1051367 to T. Langkilde.

***GRAPTEMYS PSEUDOGEOGRAPHICA PSEUDOGEOGRAPHICA* (False Map Turtle)**. USA: FLORIDA: Volusia Co.: Blue Springs State Park, 200 m E of the mouth of St. Johns River inside of the Blue Spring Run (28.94337°N, 81.341264°W, WGS84; elev. 6 m). 27 May 2011. Eric C. Munscher. Verified by Gerald R. Johnson and Kenneth L. Krysko. Florida Museum of Natural History (UF 168572). New county record (Krysko et al. 2011. Atlas of Amphibians and Reptiles in Florida. Final report, Florida Fish and Wildlife Conservation Commission, Tallahassee, USA. 524 pp.). Female (carapace length = 233 mm, straight midline plastron length = 178 mm, 927 g) captured by hand at 1000 h as we snorkeled along the center of the lower Blue Spring Run toward the St. Johns River. The abundance of algae on the carapace (60% of surface area) suggests this is not a recently released captive. This is the first reported occurrence of *G. p. pseudogeographica* in the St. Johns River Basin. This non-indigenous turtle may be in the early phase of an introduction that may require monitoring. In Florida, *G. p. pseudogeographica* is commonly sold in pet stores and may replace the Red-eared Slider (*Trachemys scripta elegans*) as the most frequently released non-indigenous pet turtle. Given its omnivorous diet and the proximity to habitat types similar to its native habitat in the Missouri and Mississippi River drainages, *G. p. pseudogeographica* could potentially thrive in the St. Johns River Basin.

ERIC C. MUNSCHER, Department of Natural Resources, SWCA Environmental Consultants, Houston, Texas 77068, USA (e-mail: emunscher@

swca.com); **J. BRIAN HAUGE**, Peninsula College, Port Angeles, Washington 98362, USA (e-mail: biologybrian@gmail.com); **KATY BERGIN**, Blue Springs State Park, 2100 West French Ave., Orange City, Florida, USA (e-mail: megan.keserauskis@dep.state.fl.us).

***TRACHEMYS SCRIPTA ELEGANS* (Red-eared Slider)**. USA: FLORIDA: Levy Co.: Manatee Springs State Park, 0.43 km from the Manatee Springs boil (29.48859°N, 82.98005°W, WGS84; elev. 6 m). 16 August 2011. Eric C. Munscher, David Rogers, Eleanor Havens. Verified by Kenneth L. Krysko, Florida Museum of Natural History (UF 168695). New county record (Krysko et al. 2011. Atlas of Amphibians and Reptiles in Florida. Final report, Florida Fish and Wildlife Conservation Commission, Tallahassee. 524 pp.). Female (carapace length 229 mm, midline plastron length 157 mm, 546 g) captured by hand at 930 h as we snorkeled along the eastern side of the Suwannee River / Manatee Springs Spring Run outflow. The lack of algal growth on this turtle's shell might indicate a recent release; however, this area is rather remote. In Florida, *T. s. elegans* has been commonly sold in pet stores for many years and as a result has become one of the most prolifically released exotic species of turtle in Florida.

ERIC C. MUNSCHER, Department of Natural Resources, SWCA Environmental Consultants, Houston, Texas 77068, USA (e-mail: emunscher@swca.com); **DAVID ROGERS**, Peninsula College, Port Angeles, Washington 98362, USA (e-mail: kinosterni.dave@gmail.com); **ELEANOR A. HAVENS**, Western Washington University, Huxley College of the Environment, Bellingham, Washington 98255, USA (e-mail: shes_an_angel@comcast.net).

***TRACHEMYS SCRIPTA ELEGANS* (Red-eared Slider)**. USA: FLORIDA: Seminole Co.: Wekiwa Springs State Park, 0.17 km from the Wekiwa Springs boil (28.71361°N, 81.45859°W, WGS84; elev. 6 m). 26 March 2011. Eric C. Munscher, J. Brian Hauge, Joseph McDonald, and David Rogers. Verified by Kenneth L. Krysko, Florida Museum of Natural History (UF 168593). New county record (Krysko et al. 2011. Atlas of Amphibians and Reptiles in Florida. Final report, Florida Fish and Wildlife Conservation Commission, Tallahassee. 524 pp.). Female (carapace length = 242 mm, midline plastron length = 183 mm, 1023 g) captured by hand at 1030 h as we snorkeled along the eastern end of the Wekiwa Springs Lagoon. The lack of algal growth on this turtle's shell might indicate a recent release.

ERIC C. MUNSCHER, Department of Natural Resources, SWCA Environmental Consultants, Houston, Texas 77068, USA (e-mail: emunscher@swca.com; **JOSEPH McDONALD**, Western Washington University, Huxley College of the Environment, Bellingham, Washington 98255, USA; **J. BRIAN HAUGE**, (e-mail: biologybrian@gmail.com) and **DAVID ROGERS**, Peninsula College, Port Angeles, Washington 98362, USA (e-mail: kinosterni.dave@gmail.com).

SQUAMATA — LIZARDS

***ANOLIS SAGREI* (Brown Anole)**. USA: FLORIDA: Escambia Co.: Pensacola: Agriculture Interdiction Station I-10, Station 19: I-10 eastbound (30.54519°N, 87.35201°W, WGS84). 15 November 2012. Katrina Simmons and Randal St. Louis. Verified by Kenneth L. Krysko, Florida Museum of Natural History, University of Florida (UF 169126). First county interdiction and westernmost vouchered specimen for the Florida Panhandle (Krysko et al. 2011. Atlas of Amphibians and Reptiles in Florida. Final report, Project Agreement 08013, Florida Fish and Wildlife Conservation Commission, Tallahassee. 524 pp.). Currently, *A. sagrei* is not known to be established in Escambia Co., but is present in adjacent Santa Rosa Co. and at least 54 other Florida counties (Krysko et al. 2011, *op. cit.*).

One adult male was confiscated from a truck delivering horticultural plants from Alvin, Brazoria Co., Texas, where non-indigenous *A. sagrei* is previously established (McCoid 2006. Herpetol. Rev. 37:361). The specimen was originally turned in to Division of Plant Industry, Florida Department of Agriculture and Consumer Services, Gainesville, Florida; Entomology Log No. E2012-8695.

The vehicle's destination was Boynton Beach, Palm Beach Co., Florida, where an established population of this Caribbean anole already exists (Krysko et al. 2011, *op. cit.*), and potentially could have contributed to the known genetic admixture among various invasive populations (Kolbe et al. 2004. Nature 431:177–181; Kolbe et al. 2008. Biol. Lett. 4:434–437).

I thank Dyrana Russell for details regarding confiscation locality.

LOUIS A. SOMMA, Florida Museum of Natural History, University of Florida, Gainesville, Florida 32611, USA; e-mail: somma@ufl.edu.

***HEMIDACTYLUS TURCICUS* (Mediterranean Gecko)**. USA: ILLINOIS: Jackson Co.: Carbondale (37.72031°N, 89.21746°W; WGS84). 15 July 2011. M. Rowland, B. Sadie, and Matt R. Whiles. Verified by Ronald A. Brandon. Southern Illinois University Fluid Vertebrate Collection (SIUC R-3424). New county record, extending range ca. 37 km from Williamson Co. record (McDowell et al. 2006. Herpetol. Rev. 37:481).

McDowell et al. (2006, *op. cit.*) documented the first state occurrence of this gecko in adjacent Williamson Co. Juvenile and adult *H. turcicus* were again found at the Williamson Co. site in 2011 and 2012. The presence of a second population (Jackson Co.) indicates that *H. turcicus* is firmly established and expanding its range in southern Illinois. Four adults were found after dark on a building in downtown Carbondale. Five adults and two juveniles were found at the same locality on 28 July 2012.

MATT R. WHILES, Southern Illinois University, Department of Zoology and Center for Ecology, Carbondale, Illinois 62901-6501, USA (e-mail: mwhiles@zoology.siu.edu); **WILLIAM T. McDOWELL**, Southern Illinois University, School of Medicine, Carbondale, Illinois 62901, USA (e-mail: tmcdowell@siumed.edu); **AARON C. GOOLEY**, Southern Illinois University, Cooperative Wildlife Research Laboratory, Carbondale, Illinois 62901, USA (e-mail: acgooley@siu.edu).

***HEMIDACTYLUS TURCICUS* (Mediterranean Gecko)**. USA: KENTUCKY: Kenton Co.: Taylor Mill (39.016460°N, 84.507355°W; WGS 84). 4 June 2012. Paul J. Krusling and Heather Boor Mitchell. Verified by Jeffrey G. Davis. Cincinnati Museum Center Herpetology Collection (CMC 12339–12341). The first documented records for the Commonwealth of Kentucky (Kraus. 2009. Alien Reptiles and Amphibians: A Scientific Compendium and Analysis. Invading Nature: Springer Series in Invasion Ecology No. 4. Springer, New York. 563 pp.).

In addition to the three vouchers, at least 15 individuals, including large, apparently gravid females, and juveniles were seen on, or near, a strip shopping center in Taylor Mill, Kentucky between 2200 and 2300 h. The source of this population is unknown, but may be the result of escapes from a local pet shop or accidental introduction from a grocery store located at the site. This population has persisted for at least seven years (HBM, pers. obs.).

PAUL J. KRUSLING, Geier Collections and Research Center, Cincinnati Museum Center, 1301 Western Avenue, Cincinnati, Ohio 45203, USA,

(e-mail: pkrusling@gmail.com); **HEATHER BOOR MITCHELL**, Scott High School, 5400 Old Taylor Mill Road, Taylor Mill, Kentucky 41015, USA (e-mail: Htmz6911@yahoo.com).

***PODARCIS MURALIS* (Common Wall Lizard)**. USA: OHIO: Butler Co.: Hanover Twp., near intersection of Ross Hanover and Black Roads (39.39158°N, 84.63873°W; WGS 84). 11 November 2012. J. G. Davis and J. W. Ferner. Verified by Paul Krusling. CMC 12360–12361 (with tissues). New county record (Wynn and Moody 2006. Ohio Turtle, Lizard and Snake Atlas. Ohio Biol. Surv. Misc. Contrib. No. 10). This is an established breeding population that occupies a south-facing, stacked-rock wall approximately 0.75 m high and 7 m long.

Wall lizards were introduced in eastern Cincinnati (Hamilton Co.), Ohio from northern Italy in the early 1950s (Deichsel and Gist 2001. Herpetol. Rev. 32[4]:230–232). It is likely these were also released at this additional site as no known dispersion corridors such as railroad beds (Hedeen and Hedeen 1999. Herpetol. Rev. 30[1]:57–58) and river drainages are nearby. This metapopulation now includes Hamilton Co., Ohio to the south and Boone, Campbell, and Kenton counties across the Ohio River in northern Kentucky (Kraus. 2009. Alien Reptiles and Amphibians: A Scientific Compendium and Analysis. Invading Nature: Springer Series in Invasion Ecology No. 4. Springer, New York. 563 pp.).

JOHN W. FERNER, Department of Biology, Thomas More College, Crestview Hills, Kentucky 41017 USA (e-mail: john.ferner@thomasmore.edu); **JEFFREY G. DAVIS**, Geier Collections and Research Center, Cincinnati Museum Center, 1301 Western Ave., Cincinnati, Ohio 45203, USA (e-mail: ohiofrogs@gmail.com).

SQUAMATA — SNAKES

***AGKISTRODON CONTORTRIX* (Copperhead)**. USA: TENNESSEE: Weakley Co.: Shades Bridge Rd, 4 km E of Hwy 45E (36.13395°N, 88.78111°W; NAD 83). 10 August 2011. Jeremy Dennison. Verified by A. Floyd Scott. Austin Peay State University Museum of Zoology (APSU 19194). First county record (Scott and Redmond 2008. Atlas of Reptiles in Tennessee. The Center for Field Biology, Austin Peay State University, Clarksville, Tennessee. http://www.apsu.edu/reptatlas [updated 7 August 2012; accessed 4 December 2012]).

Voucher specimen collected under the authority of the Tennessee Wildlife Resources Agency; field work supported by State Wildlife Grant (SWG) funding under the authority of the U.S. Fish and Wildlife Service.

ROBERT COLVIN (e-mail: Rob.Colvin@tn.gov) and **JEREMY DENNISON** Tennessee Wildlife Resources Agency, Region I, 200 Lowell Thomas Drive, Jackson, Tennessee 38301, USA (e-mail: Jeremy.Dennison@tn.gov).

***CLONOPHIS KIRTLANDII* (Kirtland's Snake)**. USA: INDIANA: Fayette Co.: Connorsville Township (39.6566°N, 85.2386°W; NAD 83). 20 August 2012. John Cannarella. Field Museum of Natural History (FMNH 282154). Jackson Co.: Grassy Fork Township (38.76201°N, 85.92413°W; NAD 83). 26 April 2012. Sarabeth Klueh and Jason Mirtl. FMNH 282784.

These are new county records (Minton 2001. Amphibians and Reptiles of Indiana. 2nd ed., revised. Indiana Academy of Science. vii + 404 pp.). Both specimens were verified by Alan Resetar.

SARABETH KLUEH, Wildlife Diversity Section, Indiana Department of Natural Resources Division of Fish and Wildlife, 553 E. Miller Drive, Bloomington, Indiana 47401, USA; e-mail: sklueh@dnr.IN.gov.

***CROTALUS HORRIDUS* (Timber Rattlesnake)**. USA: ARKANSAS: Nevada Co.: Vicinity of Pleasant Plains, approximately 9.6 km N of Prescott (33.880825°N, 93.440531°W; WGS 84, elev. ~ 106 m) on St. Hwy 19, September 2008. Jessica F. Crump. Verified by Malcolm L. McCallum. Two adult males (Arkansas State University Museum of Zoology Herpetological Collection—ASUMZ 31289, 31290) collected DOR within a week of each other at nearly the same spot. First county records (Trauth et al. 2004. The Amphibians and Reptiles of Arkansas. Univ. Arkansas Press, Fayetteville. 421 pp.), approximately 27 air km from nearest known record in Pike Co.

Live Timber Rattlesnakes have been seen crossing St. Hwy 19 at this particular point on several other occasions. Predominate surrounding habitat is low rolling hills of Loblolly Pine (*Pinus taeda*) plantations interspersed with bottomland hardwood riparian areas located in the northernmost region of the West Gulf Coastal Plain ecological system

***FARANCIA ERYTROGRAMMA ERYTROGRAMMA* (Common Rainbow Snake)**. USA: SOUTH CAROLINA: Darlington Co.: Lauthers Lake, 13.3 km ENE Darlington (34.32889°N, 79.72456°W; WGS 84). 23 March 2012. Jeffrey D. Camper and Christopher Johnson. Verified by Stanlee Miller. Clemson University Vertebrate Collections (CUSC 2850, voucher photograph). New county record (Camper 2010. Herpetol. Rev. 41:385–386). This juvenile specimen (~0.5 m SVL) was discovered under a log in a seepage area approximately 1 m from a small stream at 1430 h. This species has been previously observed in adjacent Florence Co. at Lynches River County Park, 11 km S Florence (Camper 2010, *op. cit.*).

CHRISTOPHER JOHNSON (e-mail: cjohnson6090@g.fmarion.edu) and **JEFFREY D. CAMPER** (e-mail: jcamper@fmarion.edu), Department of Biology, Francis Marion University, Florence, South Carolina, 29506, USA.

***HETERODON PLATIRHINOS* (Eastern Hog-nosed Snake)**. USA: TENNESSEE: Henderson Co.: 2410 Hwy 104 S near Lexington (35.5879°N, 88.3559°W; NAD 83). 5 June 2011. Shannon Gigliotti and Rob Colvin. Verified by A. Floyd Scott. Austin Peay State University Museum of Zoology (APSU 19361,19362 photo vouchers). First county record (Scott and Redmond 2008. Atlas of Reptiles in Tennessee. The Center for Field Biology, Austin Peay State University, Clarksville, Tennessee. http://www.apsu.edu/reptatlas [updated 7 August 2012; accessed 4 December 2012]). Two individuals photographed on the Gigliotti Farm.

Photo voucher collected under the authority of the Tennessee Wildlife Resources Agency; field work supported by State Wildlife Grant (SWG) funding under the authority of the U.S. Fish and Wildlife Service.

ROBERT COLVIN Tennessee Wildlife Resources Agency, Region I, 200 Lowell Thomas Drive, Jackson, Tennessee, 38301, USA; e-mail: Rob.Colvin@tn.gov

***HYDROPHIS CYANOCINCTUS* (Annulated Sea Snake)**. BANGLADESH: COX'S BAZAR DISTRICT: Sonadia Island (21.493541°N, 91.853424°E; WGS 84). 15 August 2012. Photographic voucher, Raffles Museum of Biodiversity Research, National University of Singapore (ZRC [IMG] 2.175 a-b). Specimen collected by local fishermen ~1.5 km offshore. SVL 135 cm, tail length 14.4 cm. Verified by Aaron Savio Lobo. First record for Sonadia Island, a ca. 4900-ha barrier island in SE Bangladesh, NW of Cox's Bazaar town. Island supports some of the last remaining patches of natural mangrove forest in SE Bangladesh. Khan (2008. Protected Areas of Bangladesh—A Guide to Wildlife. Nishorgo Program, Bangladesh Forest Department, Dhaka, Bangladesh. 293 pp.) mentioned its occurrence in Bangladesh, but with no locality information or voucher specimen.

SHAHRIAR CAESAR RAHMAN, Department of Environmental Science, Independent University, Dhaka, Bangladesh (e-mail: caesar_rahman2004@yahoo.com); **A.H.M. ALI REZA**, Division of Biological and Physical Sciences, Delta State University, Cleveland, Mississippi 38733, USA (e-mail: areza@deltastate.edu).

***LAMPROPELTIS GETULA* (Eastern Kingsnake)**. USA: TENNESSEE: Lauderdale Co.: Hwy 19 at Ripley Elementary School (35.74099°N, 89.53758°W; NAD 83). 29 August 2011. Wade Hendren. Verified by A. Floyd Scott. Austin Peay State University Museum of Zoology (APSU 19195). First county record (Scott and Redmond 2008. Atlas of Reptiles in Tennessee. The Center for Field Biology, Austin Peay State University, Clarksville, Tennessee. http://www.apsu.edu/reptatlas [updated 7 August 2012; accessed 4 December 2012]).

Voucher specimen collected under the authority of the Tennessee Wildlife Resources Agency; field work supported by State Wildlife Grant (SWG) funding under the authority of the U.S. Fish and Wildlife Service.

ROBERT COLVIN, (e-mail: Rob.Colvin@tn.gov) and **WADE HENDREN** (e-mail: Wade.Hendren@tn.gov), Tennessee Wildlife Resources Agency, Region I, 200 Lowell Thomas Drive, Jackson, Tennessee 38301, USA.

***MICRURUS BERNADI* (Saddled Coralsnake)**. MÉXICO: HIDALGO: Municipality of Huazalingo: near San Juan (20.98861°N, 98.5044°W; WGS84), 1249 m elev. 20 March 2007. Raúl Valencia and Jorge Valencia-Herverth. Verified by Irene Goyenechea. Colección Herpetológica Fotográfica, Centro de Investigaciones Biológicas, Universidad Autónoma del Estado de Hidalgo (CHCIB 03). First record for municipality, extending range 16.16 km E from nearest record in the Municipality of Tlanchinol, Hidalgo (Ramírez-Bautista et al. 2010. Lista Anotada de los Anfibios y Reptiles del Estado de Hidalgo, México. Universidad Autónoma del Estado de Hidalgo, CONABIO. x + 104 pp.). The snake was found on the ground in tropical deciduous forest.

JORGE VALENCIA-HERVERTH and **LEONARDO FERNÁNDEZ-BADILLO** (e-mail: cyrtopsis@hotmail.com), Centro de Investigaciones Biológicas (CIB), Universidad Autónoma del Estado de Hidalgo, A.P. 1-69 Plaza Juárez, Pachuca, Hidalgo, México.

***MICRURUS DISTANS* (West Mexican Coralsnake)**. MEXICO: SONORA: Municipio de Sahuaripa: Sierra Los Chinos, 17.5 km NNE Sahuaripa (29.20624°N, 109.19078°W; WGS84), 875 m elev. 13 April 2010. James C. Rorabaugh, Abigail D. King, Carmina Gutiérrez González, and Miguel A. Gómez Ramírez. Verified by G. Bradley. UAZ 57239-PSV. New municipality record, northernmost locality for this species, and extends the range in Sonora 100 km NNW from the previous northern range limit near Río Maycoba reported by Van Devender and Enderson (2007. Herpetol. Rev. 38:488). The specimen was found while crossing a dirt road at about 1000 h on a steep rocky slope in foothills thornscrub; air temperature was 27°C.

KIM BAILEY, 114 Pembroke Ave., Nashville, Tennessee, 37205, USA; e-mail: kim.bailey@nashville.gov.

***TANTILLA HOBARTSMITHI* (Smith's Black-headed Snake)**. USA: TEXAS: Ward Co.: 1200 E. Sealy Ave., 1.25 km E of St. Hwy 18 (31.58778°N, 102.890556°W; NAD83). 13 May 2012. Matthew Anderson. Verified by Stanley Fox. Oklahoma State University (OSUS R6160). New county record. The closest known localities are immediately west in Reeves Co. (Dixon and Werler 2005. Texas Snakes: A Field Guide. University of Texas Press, Austin. 364 pp.). The snake was found under debris, in the parking lot of an abandoned hotel. The hotel has been empty for several years, with sand and grass beginning to cover the former parking areas.

MATTHEW L. ANDERSON, **CAMERON W. HODGES**, and **ENRIQUE SANTOYO-BRITO**, Zoology Department, Oklahoma State University, Stillwater, Oklahoma 74078, USA (e-mail: matt.anderson@okstate.edu).

***THAMNOPHIS EQUES* (Mexican Gartersnake)**. USA: ARIZONA: Mohave Co. / La Paz Co. border: Bill Williams River, approximately 22.5 km E from the Highway 95 crossing of the Bill Williams River (34.25279°N, 113.85513°W; NAD 83). June 2012. Taylor B. Cotten and Jonathan D. Miller. Verified by G. L. Bradley (UAZ 57451). Range extension (Brennan and Holycross 2006. A Field Guide to Amphibians and Reptiles in Arizona. Arizona Game and Fish Department, Phoenix, Arizona. 150 pp.). The closest known extant population occurs approximately 178 km to the northeast in Yavapai Co. and does not share a drainage system with the Bill Williams River until the Gila River-Colorado River confluence approximately 180 km SW of this specimen. Closer populations formerly occurred on the Colorado River based on specimens collected east of Fort Mohave in 1904 and Yuma in 1890—approximately 110 km NW in Mohave Co. and 184 km SW in Yuma Co., respectively. More recently (1981), a verified population was located on the Agua Fria River 156 km E in Maricopa and Yavapai counties. However, these populations have been extirpated.

TAYLOR B. COTTEN, **JONATHAN D. MILLER,** and **DAVID D. GRANDMAISON**, Arizona Game and Fish Department, 5000 W. Carefree Highway, Phoenix, Arizona 85086, USA (e-mail: TCotten@azgfd.gov).

***TRIMORPHODON TAU* (Mexican Lyresnake)**. MEXICO: SONORA: Municipality of Sahuaripa: Northern Jaguar Reserve, Rancho La Ventana, 32 km NNE Sahuaripa (29.32245°N, 109.10180°W; NAD 27 CONUS), ca. 1000 m elev. 6 June 2008. James C. Rorabaugh. Verified by T. J. Devitt and T. J. LaDuc. UAZ 57047-PSV. New municipality record, extending range 143 km N of closest known locality in eastern Sonora (UAZ 42839), 8.0 km S Nuri on road to Tesopaco (= Rosario) (Rorabaugh 2008. J. Arizona-Nevada Acad. Sci. 40:20–65). Specimen was in a mesquite-lined arroyo in thornscrub.

JAMES C. RORABAUGH, P.O. Box 31, Saint David, Arizona 85630, USA; e-mail: jrorabaugh@hotmail.com.

NATURAL HISTORY NOTES

The Natural History Notes section is analogous to Geographic Distribution. Preferred notes should 1) focus on observations in the field, with little human intrusion; 2) represent more than the isolated documentation of developmental aberrations; and 3) possess a natural history perspective. Individual notes should, with few exceptions, concern only one species, and authors are requested to choose a keyword or short phrase which best describes the nature of their note (e.g., Reproduction, Morphology, Habitat, etc.). Use of figures to illustrate any data is encouraged, but should replace words rather than embellish them. The section's intent is to convey information rather than demonstrate prose. Articles submitted to this section will be reviewed and edited prior to acceptance.

Electronic submission of manuscripts is requested (as Microsoft Word or Rich Text format [rtf] files, as e-mail attachments). Figures can be submitted electronically as JPG files, although higher resolution TIFF or PDF files will be requested for publication. Please DO NOT send graphic files as imbedded figures within a text file. Additional information concerning preparation and submission of graphics files is available on the SSAR web site at: http://www.ssarherps.org/HRinfo.html. Manuscripts should be sent to the appropriate section editor: **Charles W. Painter** (amphibians; charles.painter@state.nm.us); **James Harding** (turtles; hardingj@msu.edu); **Jackson D. Shedd** (crocodilians, lizards, and *Sphenodon*; Jackson.Shedd@gmail.com); and **John D. Willson** or **David A. Steen** (snakes; hr.snake.nhn@gmail.com).

Standard format for this section is as follows: **SCIENTIFIC NAME** in bold, capital letters; standard English name in parentheses with only first letter of each word capitalized (if available, for the United States and Canada as it appears in Crother [ed.] 2012. *Scientific and Standard English Names of Amphibians and Reptiles of North America North of Mexico, with Comments Regarding Confidence in Our Understanding, 7th ed.* Herpetol. Circ. 39:1–92, available from SSAR Publications Secretary, ssar@herplit.com; for Mexico as it appears in Liner and Casas-Andreu 2008. *Standard Spanish, English and Scientific Names of the Amphibians and Reptiles of Mexico.* Herpetol. Circ. 38:1–162); **KEY WORD(S)** referring to the content of the note in bold, capital letters; content reporting observations and data on the animal; place of deposition or intended deposition of specimen(s), and catalog number(s) if relevant. Then skip a line and close with author name(s) in bold, capital letters (give names and addresses in full—spell out state names—no abbreviations, e-mail address after each author name/address for those wishing to provide it—e-mail required for corresponding author). References may be briefly cited in text (refer to this issue for citation format and follow format closely). One additional note about the names list (Crother 2012) developed and adopted by ASIH-HL-SSAR: the role of the list is to standardize English names and comment on the current scientific names. Scientific names are hypotheses (or at least represent them) and as such their usage should not be dictated by a list, society, or journal.

Recommended citation for notes appearing in this section is: Goldberg, S. R., and C. R. Mahrdt. 2012. *Bogertophis rosaliae*: reproduction. Herpetol. Rev. 43:655.

CAUDATA — SALAMANDERS

***AMBYSTOMA CINGULATUM* (Frosted Flatwoods Salamander). COURTSHIP and OVIPOSITION.** Following the passage of a frontal rain system on the evening of 3 Nov 2010, I observed two loose congregations of adult *Ambystoma cingulatum* within a dry pond basin in the Apalachicola National Forest, Liberty Co., Florida, USA. The two congregations each consisted of 5–8 males and 1–2 females and were about 20 m apart within the wetland basin. The pond was a shallow depression with a sparse overstory of Pond Cypress (*Taxodium ascendens*) and tupelo (*Nyssa* sp.) and a midstory dominated by Apalachicola St. John's Wort (*Hypericum chapmanni*). Salamanders were associated with comparatively open areas carpeted with dense patches of herbs, primarily Fleabane (*Erigeron vernus*), and pipeworts (*Eriocaulon compresum* and *E. decangulare*), but with scattered occurrences of various bunch grasses and pitcher plants (*Sarracenia* spp.). Male salamanders prowled actively among the herb layer and crawled in a haphazard manner, frequently doubling back or crawling through areas they had visited previously. The few gravid females were observed to be nearly motionless within the herb layer, one disappearing into a nearby crayfish burrow after a few minutes of observation. No interactions were noted between male and female salamanders, even though crawling males passed within a few centimeters of females. Salamander movement waned after 2300 h and few salamanders were seen above ground as the rain had long since stopped and the sky finally cleared at 2400 h.

Following the passage of a cold front on the evening of 16 Nov 2010, I returned to the same location and immediately observed a pair of salamanders engaged in courtship at 2005 h. The male salamander crawled alongside, just behind, and to the side of a large gravid female for 5–7 seconds, with its head at the level of her rear legs, until the female came to a stop. The male then crawled forward of the female, positioned its rear legs at the level of her head, and made several short jerking motions with its body before undulating or "wagging" its tail slowly back and forth over the anterior half of the female's body. The female would resume crawling for several centimeters before it would again stop and the male would then reposition itself for a repeated bout of tail wagging. Three cycles of this behavior were observed over the duration of 4 min before both salamanders were obscured from view by a thick clump of sedges. I assume it was at this time that spermatophore exchange occurred as the female salamander emerged from the sedges alone ca. 30 min later and crawled slowly but directly to her oviposition site about

1 m away beneath a large pipewort at the base of a cypress knee where she then remained for ca. 1.5 h. After crawling away and disappearing down a crayfish burrow, a cluster of four freshly deposited eggs was visible beneath the decumbent leaves of the pipewort. Although the clay substrate was nearly saturated, the nearest standing water was a small puddle about 2 m away which contained only a few centimeters of water.

Also during this time, another 8 males and 2 gravid females were observed. Males were crawling quickly within the herb layer while females were crawling slowly, pausing often, or remaining motionless but no other incidences of courtship were observed. All salamander movement stopped shortly after 2300 h. Approximately 15 other egg deposition sites were observed nearby in various stages of early development, all of which were above water and beneath the leaves of rosette-forming herbs. I was able to photograph courtship, egg deposition, and the freshly laid eggs and the photos can be made available upon request.

The four focal eggs' development was followed in the field and I observed and photographed them at 14, 24, 30, and 46 days. The eggs had developed to Harrison Developmental Stage 37 by day 14, were at stage 38 on day 24, stage 39 on day 30. The eggs were finally inundated by rising water levels on day 46 (31 Dec), when larvae hatched at stage 45 from two of the four eggs.

These observations of *A. cingulatum* courtship are the first documented for the federally threatened species and they confirm that it occurs terrestrially, as suspected by previous researchers. Additionally, these observations confirm terrestrial egg deposition as reported by Anderson and Williamson (1976. Herpetologica 32[2]:214–221), whose conclusions were disputed by Ashton and Ashton (2005. *In* Meshaka, and Babbitt [eds.], Amphibians and Reptiles: Status and Conservation in Florida, pp. 62–73. Krieger Publ., Malabar, Florida).

E. PIERSON HILL, Department of Biological Science, Florida State University, 319 Stadium Drive, Tallahassee, Florida 32306-4295, USA; e-mail: phill@bio.fsu.edu.

***AMBYSTOMA MACULATUM* (Spotted Salamander). TERRESTRIAL OVIPOSITION.** *Ambystoma maculatum* frequents permanent or ephemeral water bodies in the spring for breeding where females oviposit ca. 50 eggs on submerged vegetation or aquatic substratum (Petranka 2010. Salamanders of the United States and Canada. Smithsonian Inst. Press, Washington DC. 587 pp.). On 26 and 27 April 2012, walking surveys were conducted around the perimeter of Lost Ray Lake (45.591130°N, 78.537941°W), Algonquin Provincial Park, Ontario, Canada, as part of an ongoing study to assess breeding activity of *A. maculatum*. On two separate surveys, terrestrial oviposition was noted for *A. maculatum*. We propose multiple explanations for our observations as well as draw comparisons with the terrestrial nesting habits of other *Ambystoma*.

The first egg mass was found 26 April under a log (Log A) ca. 4.8 m from the north shoreline of Lost Ray Lake. Upon flipping Log A an adult female *A. maculatum*, which appeared to have recently oviposited, was found in a shallow depression beside a small white globular mass containing four fertilized eggs (Fig. 1). Log A was overgrown with *Sphagnum* sp. moss and partially submerged in water-saturated mud. Ground surface temperature underneath the log was 3.3°C, nearest water temperature was 4.0°C and ambient air temperature was -1.3°C. The second egg mass (Log B) also contained four opaque eggs and was found 27 April ca. 27.9 m from the east shore of Lost Ray Lake. No adult *A. maculatum* were found in the immediate vicinity of the second log, however several *A. maculatum*, *A. laterale*, and *Pseudacris cruicifer* were found in the surrounding area. Log B was situated loosely on top of a bed of long flattened grass in the lake floodplain. Although moist, the mud below Log B was much dryer compared to Log A. Crustose lichen was present on Log B, but no mosses were present. Ground surface temperature beneath Log B was 1.2°C, nearest water temperature was 4.3°C and ambient air temperature was 0°C.

PHOTO BY SEAN BOYLE

FIG. 1. Terrestrial oviposition of female *Ambystoma maculatum* (Log A) with a four-embryo egg mass (upper right). An isolated gelatinous capsule lacking an embryo is pictured center.

While terrestrial egg-laying is relatively commonplace in North American salamanders, most notably within Plethodontinae, only two ambystomatids exhibit terrestrial oviposition: *A. cingulatum* and *A. opacum* (Petranka 2010, *op. cit.*). To our knowledge this is the first report of terrestrial oviposition for *A. maculatum*. It seems unfavorable for female *A. maculatum* to lay eggs terrestrially. This claim is supported by the fact that in both instances the egg masses numbered only four eggs each, far below the species typical clutch size of 50 eggs (Petranka 2010, *op. cit.*). Furthermore, eggs laid terrestrially risk desiccation and freezing. The eggs of *A. maculatum* are well noted as sharing a symbiotic relationship with green algae, conferring several benefits including gaseous exchange (Kerney 2011. Symbiosis 54:107–117). Presumably eggs laid in dark terrestrial environments would not experience benefits provided by an algal symbiont.

One possible explanation for the terrestrial oviposition is that laying occurred secondarily (i.e., each female already oviposited their main egg mass[es] in the nearby water body). In a final attempt to reduce the energetic cost associated with retaining the eggs that remained in the oviduct, each female may have laid them shortly after migration away from Lost Ray Lake. The eggs also could have been laid due to stressful conditions (e.g., predation risk, environmental stressors). In 2012, Algonquin Provincial Park experienced the earliest lake ice out and forest thaw dates on record, nearly a month in advance of the mean thaw date (Fraser and Tozer 2012. Ice-out dates for Lake Opeongo. Unpublished report, Algonquin Park Visitor Centre Library #6097). Early lake and forest thaw followed by a period of

low precipitation and a cold snap altered the spring 2012 migration and breeding phenology of pond-breeding salamanders in Algonquin (SPB and PDM, pers. obs.). We speculate that unusual environmental conditions may have prompted stress-induced oviposition or else mixed physiological messages spurring abnormal reproduction.

The nest site features reported here share similarities with those documented for other terrestrial laying mole salamanders. *Ambystoma cingulatum* and *A. opacum* have been reported to oviposit beneath logs, grasses, and moist vegetation (Anderson and Williamson 1976. Herpetologica 32:214–221; Bishop 1941. New York State Mus. Bull. 324:1–365; Jackson et al. 1989. Can. J. Zool. 67: 2277–2281). Lastly, both *A. cingulatum* and *A. opacum* depend on rising floodwaters to trigger hatching and allow development of gilled larvae. Perhaps the floodplain was deemed a suitable nesting site and actively chosen by *A. maculatum* females because of impending potential for flooding.

Financial support provided by the Friends of Algonquin Park. Much thanks for in-kind support owing to the Algonquin Wildlife Research Station, R. Eckenswiller, and B. Steinberg. Special thanks to G. J. Tattersall for his dedication to the Algonquin salamander project and D. LeGros for his constructive manuscript review.

AMBYSTOMA OPACUM **(Marbled Salamander). COLORATION.** *Ambystoma opacum* is a medium-sized, stout-bodied salamander that has a ground color of black with conspicuous white or gray crossbars across the dorsum (Petranka 1998. Salamanders of the United States and Canada. Smithsonian Inst. Press, Washington, D.C. 587 pp.). They are common throughout the southeastern United States, yet are rarely seen due to their reclusive habits (Petranka 1998, *op. cit.*; Trauth et al. 2004. The Amphibians and Reptiles of Arkansas. Univ. Arkansas Press, Fayetteville. 421 pp.). Herein, we report an unusual color morph of an adult *A. opacum*.

On 29 Sept 2012, we captured a total of 14 *A. opacum* at ca. 2100 h crossing a paved two-lane road (2.5 km N Wesson, Union Co., Arkansas, USA; 33.143440°N, 92.771521°W) migrating to breeding sites during a rainstorm. Thirteen of these had the typical color pattern; however, a single adult had a unique dorsal color pattern. This adult male (50 mm SVL) did not express the typical crossbars across the dorsum (Fig. 1). We deposited this individual within the Arkansas State University Museum of Zoology Herpetology Collection (ASUMZ 32341). Some individuals lack the crossbands and instead exhibit a morph variation consisting of longitudinal stripes (Dundee and Rossman 1989. The Amphibians and Reptiles of Louisiana. Louisiana State Univ. Press, Baton Rouge. 300 pp.; Trauth and Richards 1988. Bull. Chicago Herpetol. Soc. 23:87). However, this is the first report of the color morph that we illustrate herein.

FIG. 1. Two morphs of *Ambystoma opacum* showing typical morph (above) and unusual morph (below) collected on 29 September 2012 in Union Co., Arkansas, USA.

ANEIDES AENEUS **(Green Salamander). COLOR VARIATION.** Anomalous colors and color variants in amphibians are well known and widely reported for several genera such as *Ambystoma*, *Plethodon*, *Pseudotriton*, and *Rana* (Bechtel 1995. Reptile and Amphibian Variants: Colors, Patterns, and Scales. Krieger Publ., Malabar, Florida. 224 pp.; McDonald et al. 2011. Herpetol. Rev. 42:405–406; Mendyk et al. 2010. Herpetol. Rev. 41:189–190; Mitchell and Mazur 1998. Northeast. Nat. 5:367–369; Larson and Muller 2011. Herpetol. Rev. 42:406; Simpson and Wilson 2010. Herpetol. Rev. 41:185–186). However, only a few similar reports exist in the published literature for *Aneides* spp., and they pertain to albino *A. flavipunctatus* (Hensley 1959. Publ. Mus. Michigan State Univ. 1[4]:135–159; Seeliger 1945. Copeia 1945:122) and *A. ferreus* (= *vagrans*) (Dyrkacz 1981. Herpetol. Circ. 11:1–31; Houck 1969. Herpetologica 25:54).

Unlike most of its West Coast congeners, *A. aeneus* coloration typically includes bright green, "lichenlike" color patches on a dark gray to black dorsum; the color pattern extends onto the tail and legs (Petranka 1998. Salamanders of the United States and Canada. Smithsonian Institution Press, Washington, D.C. 587 pp.). Here, we describe what we believe to be the first examples of extreme color variation in *A. aeneus* with two observations for two individuals in North Carolina whose conditions may be described as "xanthic" (i.e., yellow pigmentation exhibited), "hypomelanistic" (i.e., reduced pigmentation exhibited) (Simpson and Wilson 2010, *op. cit.*) and/or "amelanistic" (i.e., no pigmentation exhibited). These conditions may be attributed to nonfunctioning or defective chromatophores, or pigment cells, in the skin (Bechtel 1995, *op. cit.*).

A xanthic and/or hypomelanistic adult female (4.5 cm SVL, 10.8 cm TL) was found 4.3 airline km NE Cedar Mountain, Transylvania Co., North Carolina, USA, in a rock outcrop in a large rock field across a mountain ridge top in mixed oak, hardwood, and pine forest on 7 April 2011 (Fig. 1A). The individual had normal-shaped patterns on the dorsum, legs, and tail, but they were faint yellow in color. The body exhibited reduced coloration and appeared translucent pink overall, with a wash of blue color evident on the ventral surface. Two normal-colored conspecifics were also found in this same rock outcrop (Fig. 1B). Out of four subsequent site visits from April–July 2011, this female was seen three more times, with normal colored conspecifics on each occasion.

An amelanistic, gravid adult female (12.7 cm TL, 6.3 cm SVL, # eggs visually estimated $\geq$20) was found 7.3 airline km NE Cedar

FIG. 2. Photograph of an amelanistic, gravid adult female *Aneides aeneus* (Green Salamander) on boulder surface, Henderson Co., North Carolina.

Mountain, Henderson Co., North Carolina, in a large boulder in open, pine-dominated forest with scattered boulders and rock outcrops on 9 June 2011 (Fig. 2). This individual lacked all normal pattern and color and was a translucent pink overall with very faint darker splotches on its body. Four normal-colored conspecifics were also found in this boulder, including a hatchling from the previous year. Despite nine subsequent searches of this site from June–November 2011, we never found a nest belonging to this female, nor did we see her again. This second site is separated from the first by two heavily used trails and three steep, forested ravines with creeks and waterfalls. It appears that the two anomalous salamanders belonged to separate populations.

Specific coordinates for each locality are on file with the North Carolina Wildlife Resources Commission and are withheld here to protect sites.

***EURYCEA CIRRIGERA* (Southern Two-lined Salamander). INGESTED AIR BUBBLES.** Many species of amphibian larvae with developing or developed lungs are capable of breathing air, a behavior that is influenced by a variety of factors (Wells 2007. The Ecology and Behavior of Amphibians. Univ. Chicago Press, Chicago, Illinois. 1148 pp.). Air-filled lungs can alter the buoyancy of larvae, and lunged larvae can expel excess air through the mouth or gill slits (Chadwick 1950. Amer. Midl. Nat. 43:392–398; Wells 2007, *op. cit.*). During feeding, ambystomatid larvae can sometimes ingest air, which causes them to float and prevents them from swimming normally (Johnson et al. 2003. Can. J. Zool. 81:1726–1735). To our knowledge, gulping and the ingestion of air has not been recorded in larval plethodontids. In the summer of 2012, JYL observed multiple larvae of *Eurycea cirrigera* that developed gas bubbles in their intestines after they were removed from leaf-litter traps.

On 21 April 2012, JYL collected three larvae from a leaf-litter trap (Waldron et al. 2003. Appl. Herpetol. 1:23–36) and transported them via sealable plastic bags from field sites in south Mississippi to a laboratory at the University of Southern Mississippi (USM). After a ca. 30 minute hike back to the vehicle, two of the larvae were floating at the surface of the water, with both larvae containing prominent bubbles in their intestines (Fig. 1). The intestine of the third larva contained a smaller bubble, but the larva never floated. By the next afternoon, all three had lost these bubbles and were swimming normally. JYL has observed gas bubbles in the intestines inhibiting the normal swimming behavior of four other individuals captured using this method. Two of these four, collected on 28 June 2012, contained gas bubbles large enough that the anterior region of their abdomens were noticeably expanded. These are the most extreme examples observed to date; both of these larvae lost their bubbles by the next day. JYL has also observed larvae with expanded gular regions on multiple occasions *in situ*; these larvae returned to normal after a few minutes and were released. While in the field, every effort was made to collect measurements from larvae as quickly as possible and to keep all containers with larvae out of direct sunlight. Mortality did not occur in the lab with any of the larvae that exhibited these symptoms.

The most likely explanation for these observations is that the larvae ingested air bubbles, presumably due to the stress of being captured, held, and occasionally jostled over time. When in sealable plastic bags, larvae often exhibit short periods of frantic, rapid swimming near the surface of the water, with their heads frequently breaking the surface. Because some observations *in situ* occurred within only a few minutes of placing the

FIG. 1. Larva of *Eurycea cirrigera* that ingested air during handling and transport.

larvae in the plastic bags, it is not likely that gulping was induced by hypoxic water conditions, which triggers air gulping in lunged larvae (Wells 2007, *op. cit.*). It is possible that small bubbles were already present in individuals prior to their removal from litter traps, and that the process of shaking the litter trap to check the trap caused the larvae to ingest more air. It does not seem likely that bubbles were produced from within by bacteria in the gut, as the bubbles appeared rapidly. Multiple observations of extended gular regions, without the presence of bubbles in the gut, suggest that air entered through the mouth.

We do not know whether the stress experienced by the larvae was brought on by being captured, confined, jostled, exposed to light, changes in temperature, or a combination of these factors. However, during the cooler months (November–December 2011), none of 160 *E. cirrigera* larvae that were caught in litter traps, and handled and transported in a similar fashion, exhibited any symptoms of gas bubble ingestion. This suggests that temperature stress might induce air gulping. However, JYL did not observe any floating individuals during cooler months, therefore she did not check larvae for ingested bubbles. JYL caught a total of 1133 larvae of *E. cirrigera* in litter traps between April and July 2012. Of these, very few individuals exhibited expanded gular regions (i.e., likely < 2–3%), and even fewer had ingested enough air to alter their swimming abilities.

Funding for this project was provided by the National Science Foundation (Grant No. 04344) and the U.S. Geological Survey (Grant No. 04150). This project was approved by the USM Institute for Animal Care and Use Committee (No. 11061301). Specimens maintained in the lab will be deposited in the Mississippi Museum of Natural Science in Jackson, Mississippi. We thank W. Selman and J. R. Ennen for reviewing this manuscript.

***EURYCEA RATHBUNI* (Texas Blind Salamander). HABITAT.** The paedomorphic *Eurycea* clade of south central Texas is composed of 12 known species that are endemic to the Edwards Plateau (Chippindale and Hillis 2000. Herpetol. Monogr. 14:1–80). These salamanders inhabit the aqueous environments supported by the underlying Edwards Aquifer and have various morphological characteristics seemingly associated with aquatic-subterranean living (Chippindale 2000. *In* Bruce et al. [ed.], The Biology of Plethodontid Salamanders. pp. 149–150. Kluwer Academic/Plenum Publishers, New York). Adaptations to cave living are exemplified by the endangered *Eurycea rathbuni*, which has a broad head, long slender appendages, and reduced eyes and pigment

FIG. 1. Seasonal spring found at the intersection of W. Sessom Drive and State Street, San Marcos, Texas. The spring's location can be described as an urban setting, on the edge of Texas State University campus.

(Chippindale 2000, *op. cit.*). *Eurycea rathbuni* inhabits the subterranean aquifer system and the associated karst habitat of Hays Co., Texas (Chippindale and Hillis 2000, *op. cit.*). There are few accessible water sources that converge with the aquifer and sustain *E. rathbuni*. Those that do (e.g., Rattlesnake Cave) constitute the only naturally occurring habitat in which to observe the species. Most specimens are retrieved from man-made wells and pipes (e.g., artesian wells and Spring Lake). Occasionally, specimens are retrieved from seasonal and yearly springs when water pressure in the aquifer ejects them through fractures in the limestone of the Artesian Zone of the Edwards Plateau. These fractures result in sporadic springs scattered along the Edwards Plateau (Longley 1981. Inter. J. Speleol. 11:123–128). Moreover, sightings are uncommon given the species' lack of eyesight and pigment, which may make them highly susceptible to predation above ground (Chippindale and Hillis 2000, *op. cit.*).

Importantly, *E. rathbuni* inhabits inaccessible regions of the Edwards Aquifer. Specimens found as a result of high aquifer pressures provide the majority of known habitat and distribution data for the species. The paucity of specimens documented from natural water sources (caves, sinkholes, and springs) renders much of the species' natural history enigmatic. Herein we present, to the best of our knowledge, the first documented specimens salvaged from a seasonal spring in San Marcos, Texas.

On 23 March 2012 at 1332 h, a juvenile *E. rathbuni* (41.6 mm SVL, 71.1 mm total length, 13.3 mm head length, 8.3 mm head

width) was found dead in a seasonal spring at the intersection of W. Sessom Drive and State Street, located in the city of San Marcos, Hays Co., Texas, USA (29.89050°N, 097.93684°W, WGS84; elev. 177 m). The cause of death was not apparent; we speculate poor water quality or internal trauma sustained while emerging from the spring may have been responsible. Ambient water temperature of the spring was 20°C. Water depth at the entrance of the spring was ca. 24.13–25.4 cm. The specimen was found in the water ca. 1.5 m from the mouth of the spring. The specimen was salvaged via hand-held net under TPWD scientific permit number SPR-0707-1387 to RUT. A tissue sample was taken from the tail and was preserved in 90% ethanol. The remainder of the specimen was preserved in 70% ethanol. Specimen identification was verified by Paul T. Chippindale from the University of Texas at Arlington, where the specimen and tissue sample have been deposited at the Amphibian and Reptile Diversity Research Center (UTA-A 61913; Field ID, RUT 01).

We thank P. T. Chippindale for species verification, D. M. Garcia and C. Sheehy III for critical review, F. Weckerly for the use of his caliper, J. Fries, G. Longley, and A. Gluesenkamp for guidance, C. Franklin and J. Campbell for museum assistance, and A. Groeger for use of his equipment. The South Texas Herpetological Association and the East Texas Herpetological Society provided financial support.

ANURA — FROGS

***ACRIS BLANCHARDI* (Blanchard's Cricket Frog). FEIGNING DEATH.** On 21 May 2012 at Boehler Seeps and Sandhills Preserve (Atoka County, Oklahoma USA; 34.16563°N, 95.88901°W) an *Acris blanchardi* was captured in a funnel trap that had been placed along a drift fence. When the frog was first observed, it was actively jumping inside of the trap; however, when it was picked up to remove it from the trap, it immediately opened its mouth, closed its eyes, and slowly began stretching its rear legs into a fully extended position (Fig. 1). It twitched its rear legs as it extended them and continued to twitch them after they were fully extended, but otherwise it remained completely motionless until one of the authors (DTM) gently touched one of its rear feet. When touched, it quickly retracted its legs and closed its mouth (its eyes remained closed). It then sat motionless with its rear legs tucked tightly against its body, its front legs held tightly against its head, and its head pressed down against DTM's hand (the frog was in DTM's hand during this entire process). The frog remained in this position even when it was touched and rolled onto its back.

The frog was then placed upside-down into a container. It did not move for approximately ten minutes, at which point, it righted itself and began moving around in the container. When the container was opened, it jumped out and attempted to flee.

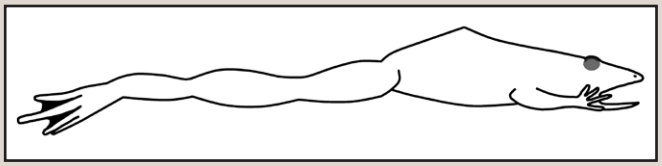

FIG. 1. A drawing of the Blanchard's Cricket Frog (*Acris blanchardi*) feigning death with its rear legs fully extended.

When it was grabbed, however, it immediately resumed its previous position with its head down, eyes closed, and limbs tucked in. When placed back on the ground, it abandoned this position and began actively fleeing. This cycle was repeated several times, however, it only opened its mouth and twitched its legs the first time that it was grabbed.

Death feigning has been previously reported in the Northern Cricket Frog (*A. crepitans*), but in that instance, the frogs remained motionless with their legs held against their body in a position that was similar to what we observed in *A. blanchardi* after touching the frog's foot, but they never extended their rear legs, twitched, or opened their mouths (McCallum 1999. Herptol. Rev. 30:90). It is possible that the differences between our observation and the observations of *A. crepitans* are a result of interspecific differences in behavior. It should be noted, however, that 161 *A. blanchardi* were captured at this site during 2012, and very few of them remained motionless with their limbs tucked in, and, other than this individual, none of them extended their rear legs, twitched, or opened their mouths. This may, therefore, be an isolated occurrence.

DONALD T. McKNIGHT (e-mail: Donald222@live.missouristate.edu), **JENNIFER L. McKNIGHT, TYLER L. DEAN**, and **DAY. B. LIGON**, Department of Biology, Missouri State University, 901 South National Avenue, Springfield, Missouri 65897, USA.

***ACRIS CREPITANS* (Northern Cricket Frog). AXANTHISM.** Variability in phenotype and expression of pigments has been well documented in some amphibians (Berns and Narayan 1970. J. Morphol. 132:169–172; Frost et al. 1986. J. Embryol. Exp. Morphol. 95:117–130; Grether et al. 2004. Biol. Rev. 79:583–610; Hoffman and Blouin 2000. Biol. J. Linn. Soc. 70:633–665; Nevo 1973. Evolution 27:353–367). On 7 Sept 2011 a juvenile *Acris crepitans* was found at Harrison Lake National Fish Hatchery in Charles City Co., Virginia, USA. Blue pigmentation was apparent on the dorsum. It was a mottled phenotype of tan/grey, green, and blue. The frog appeared to be an axanthic mosaic animal in that it was not entirely lacking xanthophores (evident in its green coloration). Many other *A. crepitans* have been seen at the hatchery across many years, by many observers, and none have been noticed to exhibit this phenotypic coloration. It is unclear as to whether the coloration was a result of diet, disease, environment, genetic variation, or hormones as all are possible causes (Berns and Narayan 1970, *op. cit.*; Chatzifotis et al. 2011. Aquaculture Nutrition 17:90–100; Frost et al. 1986, *op. cit.*; Grether et al. 2004, *op. cit.*; Hoffman and Blouin 2000, *op. cit.*; Mizusawa et al. 2011. Gen. Comp. Endocrinol. 171:75–81; Nevo 1973, *op. cit.*). It is possible that this animal may be more susceptible to disease, desiccation, or predation (Nevo 1973, *op. cit.*). A review of the literature produced no articles mentioning *A. crepitans* exhibiting the axanthic phenotype. To my knowledge, this is the first reported case of an axanthic mosaic *A. crepitans*.

J. RYAN NICCOLI, Conservation Management Institute/Virginia Polytechnic Institute and Virginia Department of Game and Inland Fisheries, 3801 John Tyler Memorial Highway, Charles City, Virginia 23188, USA; e-mail: Ryan.Niccoli@dgif.virginia.gov.

***AGALYCHNIS CALLIDRYAS* (Red-eyed Treefrog). PREDATION.** *Agalychnis callidryas* is a charismatic representative for neotropical forest conservation and tropical tourism. Predation has been observed in both the egg and larval stages, and close examination of the these life stages has increased our understanding of the ontogenetic differences in predation risk and

the mechanisms behind reducing predation risks in subadults (Warkentin 2000. Anim. Behav. 60:503–510; Warkentin 1999. Behav. Ecol. 10:251–262). Surprisingly, little has been reported on predators of the adult life stage of this species. Careful investigation for this report has resulted in general statements to identify predators of adult *A. callidryas*, with assumptions based on the feeding preferences of potential predators (Savage 2002. The Amphibians and Reptiles of Costa Rica: a Herpetofauna between Two Continents, between Two Seas. Univ. Chicago Press, Chicago, Illinois. 934 pp.).

Adult *A. callidryas* are nearly exclusively arboreal, although reproductive females seek out standing water on the ground from which to absorb moisture (presumably into their bladders), which is used to hydrate internally maturing ova (Pyburn 1970. Copeia 1970[2]:209–218). Although males occasionally are found on the margins of small pools, calling for females, our observations suggest that the majority of vocalizations come from arboreal perches. Adults typically rest during the day within the forest canopy in a shallow state of torpor, often on the underside of leaves. During evenings and rain events, adults are typically found grasping (or alight on) leaves, branches, and vegetative stalks.

The event described here represents a rarely reported observation of the predation of *A. callidryas* in the adult life stage. During the evening of 04 June 2012, in the Fincas Naturales Wildlife Refuge, Quepos, Costa Rica, Central America (9.40444°N, 84.15516°W; elev. 136 m), we detected numerous *A. callidryas* within the herbaceous vegetation throughout the refuge. The vast majority of observed individuals were above ground (approximately 0.5 to 3.0 m), and typically within vegetation of a similar color to the frog. Males vocalized frequently while engaged in saltatory movements.

While slowly walking along a transect, we observed an adult *A. callidryas* leap from the vegetation to the ground. Nearly instantaneously, a nearby adult *Leptodactylus pentadactylus* (South American Bullfrog) moved quickly through leaf litter and grasped the *A. callidryas* by the head and shoulder. The *L. pentadactylus* used its front limbs to maneuver the *A. callidryas* to grasp it by the pelvic area, with the prey's torso and head deep within the predating bullfrog's buccal cavity. When one of us attempted to photodocument the event, the *L. pentadactylus* retreated quickly with its prey into leaf litter, where it presumably consumed the *A. callidryas*.

This observation was doubly rare in that it documented terrestrial predation on adult *A. callidryas*; this and other treefrog species are presumed to be at greatly reduced risk from terrestrial predators because of their arboreal lifestyle. It can be assumed that predation on adult *A. callidryas* occurs more typically by arboreal predators, such as the *Bothriechis schlegelii* (Eyelash Viper) and juvenile *Bothrops asper* (Terciopelo) (Savage 2002, *op. cit.*), both of which were observed within the wildlife refuge during our survey effort.

ALVAREZ, The Wildlife Project, PO Box 579805, Modesto, California 95357, USA (e-mail: jeff@thewildlifeproject.com); **EMILIO SOLANA**, Fincas Naturales Wildlife Refuge, Quepos, Costa Rica (e-mail: emiliosolana@gmail.com); **SARAH M. FOSTER**, 774 5th Ave., Sacramento, California 95818, USA (e-mail: aspetree@yahoo.com).

AGALYCHNIS CALLIDRYAS (Red-eyed Treefrog), ***CRUZIOHYLA CALCARIFER*** (Gray-eyed Treefrog), ***HYPSIBOAS RUFITELUS*** (Scarlet-webbed Treefrog), and ***LEPTODACTYLUS MELANONOTUS*** (Fringe-toed Foamfrog). **PECCARY WALLOWS AS BREEDING HABITAT.** We surveyed six temporary water-filled depressions used as wallows by Collared Peccaries (*Pecari tajacu*) at La Selva Biological Station, Heredia, Costa Rica in June–July 2012. Fresh tracks confirmed that all wallows were actively used by peccaries during the study period. Four wallows contained tadpoles of one to three amphibian species. We identified tadpoles following Savage (2002. The Amphibians and Reptiles of Costa Rica: A Herpetofauna between Two Continents, between Two Seas. Univ. Chicago Press, Chicago, Illinois. 934 pp.) and Hoffmann (2005. Rev. Biol. Trop. 53:561–568). Wallow #1 contained *Agalychnis callidryas* eggs, tadpoles, and metamorphs, and *Leptodactylus melanonotus* tadpoles and an adult. Wallows #2 and #3 contained *A. callidryas* tadpoles. Wallow #4 contained *A. callidryas* tadpoles, *Hypsiboas rufitelus* tadpoles, and *Cruziohyla calcarifer* eggs, tadpoles, and an adult male. In wallows #1 and #4, we encountered *A. callidryas* and *C. calcarifer* tadpoles at various developmental stages, indicating that multiple clutches were laid at different times. We returned to wallow #1 three times over the two-month survey period, and on our final visit we noted several *A. callidryas* tadpoles at Gosner stage 41 and metamorphs at Gosner stage 42 (Gosner 1960. Herpetologica 16:183–190). We expect these tadpoles would have successfully completed metamorphosis.

To our knowledge, this is the first record of any of these species using peccary wallows as breeding habitat. We were not surprised to find *L. melanonotus* and *H. rufitelus* breeding in peccary wallows because both species seem to be habitat generalists (Savage 2002, *op. cit.*), and will use disturbed habitats such as forest fragments and cattle pastures (pers. obs.). Although *A. callidryas* also utilizes disturbed habitats, we were surprised that *A. callidryas* was the most common species encountered in wallows because this species typically breeds in temporary ponds at least an order of magnitude larger in surface area than our wallows (Donnelly and Guyer 1994. Oecologia 98:291–302). Recent observations of *A. callidryas* adults piggybacking on peccaries (Kuhn et al. 2012. Herpetol. Rev. 43:629) suggest that adult frogs may disperse among wallows by riding on the peccaries. We were even more surprised to observe multiple egg masses and tadpoles of *C. calcarifer* in wallow #4. *Cruziohyla calcarifer* is described by Savage (2002, *op. cit.*) as "…not found near either permanent or temporary ponds." *Cruziohyla calcarifer* has previously been reported using water-filled cavities in the trunks or buttresses of fallen trees (Donnelly 1987. Copeia 1987[1]:247–250). There were no treefalls visible within 30 m of wallow #4. Peccary wallows constitute a previously undescribed breeding habitat for *C. calcarifer*.

Peccaries have long been recognized as ecosystem engineers of breeding habitat for Amazonian amphibians (Gascon 1991. Ecology 72:1731–1746; Zimmerman and Bierregaard 1986. J. Biogeog. 13:133–143; Zimmerman and Simberloff 1996. J. Biogeog. 23:27–46). White-lipped Peccaries in the Amazon create wallows that hold water longer into the dry season than natural depressions. For amphibians, these wallows create novel aquatic habitats that support reproductive activities and increase the anuran biodiversity of forests with peccaries (Beck et al. 2010. J. Trop. Ecol. 26:407–414). Zimmerman and Bierregaard (1986, *op. cit.*) went so far as to recommend that the minimum size of preserves for pond-breeding amphibians in the Amazon should be determined on the basis of the size of reserve required to sustain White-lipped Peccary populations. Schlueter (2005. Herpetol. Rev. 36:160) emphasized the negative effects of peccary loss on Amazonian amphibian populations and diversity.

To our knowledge, these are the first observations of wallow-breeding by Central American amphibians. We returned to our four tadpole-containing wallows in September 2012 and noted that each wallow still contained water, new egg masses, and tadpoles, whereas two large ponds at La Selva were dry. We suggest that peccary wallows may also be important breeding habitat for many amphibian species throughout Middle America.

We thank the staff at La Selva Biological Station for logistical support. These observations were made possible by funds from the Organization for Tropical Studies and the National Science Foundation Research Experience for Undergraduates program.

REAM,** Department of Biological and Environmental Sciences, Allegheny College, 520 N. Main St., Meadville, Pennsylvania 16335, USA (e-mail: reamk@allegheny.edu).

***ALLOBATES BRUNNEUS* (Chapada Rocket Frog). PREDATION.** Some species of spiders are specialized for feeding on frogs (Lima et al. 2006. Guia de Sapos da Reserva Ducke – Amazônia Central / Guide to the Frogs of Reserva Adolpho Ducke – Central Amazonia. Áttema Design Editorial, Manaus, Brazil. 168 pp.). Herein we report predation of an adult *Allobates brunneus* by a spider in the family Ctenidae. *Allobates brunneus* is a medium-sized anuran (males 15.9–16.5 mm, females 15.4–20.0 mm) (Morales 2000. Publ. Asoc. Amigos Doñana 13:1–59), that occurs in the Amazon of Brazil from its mouth to southern Amazonas and Mato Grosso, and into extreme northern Bolivia (Frost 2011. Amphibian Species of the World: an Online Reference. Ver. 5.5 [accessed 17 October 2012]. http://research.amnh.org/vz/herpetology/amphibia/. Amer. Mus. Nat. History, New York). It inhabits the margins of lakes and pools of stagnant water in tropical rainforest; in Bolivia it is found in seasonally flooded forests. Its breeding habits are unknown, but the larvae likely develop in water (Silvano et al. 2004. *In* IUCN 2012. IUCN Red List of Threatened Species. Ver. 2012.2. <www.iucnredlist.org>. Accessed 17 Oct 2012).

On 11 Aug 2012 at 1600 h, we found an adult *A. brunneus* being preyed upon by an adult ctenid spider in leaf litter along a stream near Cave Planaltina, Brasil Novo – Pará, Brazil (3.3761°S, 52.5761°W). At the moment of observation, the *A. brunneus* was being held by the dorsolateral region by the spider. Anurans that live in the leaf litter of the forest floor have a great chance of being consumed by spiders, especially the family Ctenidae (Santana et al. 2009. Bol. Mus. Biol. Mello Leitão [N.S.] 26:59–65).

JOYCE CELERINO DE CARVALHO (e-mail: joyce.celerino@gmail.com), **EMIL JOSÉ HERNÁNDEZ-RUZ** (e-mail: emilhjh@yahoo.com), and **ELCIOMAR ARAUJO DE OLIVEIRA** (e-mail: elciomar.atractus@gmail.com.br), Laboratório de Zoologia, Faculdade de Ciências Biológicas, Universidade Federal do Pará, Campus de Altamira, Rua Coronel José Porfírio, 2515 - CEP 68.372-040 - Altamira – PA, Brazil.

***AMEEREGA FLAVOPICTA* (Yellow-painted Poison-arrow Frog). DEATH FEIGNING.** Anurans are known to feign death as a way to avoid or minimize the risk of predation (Toledo et al. 2010. J. Nat. Hist. 44[31–32]:1979–1988). This behavior is mostly displayed by non-toxic species (Toledo et al. 2010, *op. cit.*). However, this behavior has not been previously documented in *Ameerega flavopicta*, a dart-poison frog. Herein we report death-feigning behavior in *A. flavopicta*.

On 2 Feb 2006, during an anuran survey in a montane meadow (*campo rupestre*, 14.2056°S, 48.3811°W, WGS 84; elev. 353 m) near a palm swamp at Serra da Mesa, municipality of Niquelândia, Goiás state, central Brazil, we captured an adult male *A. flavopicta*. When handled to take photographs, it turned its belly up, with the arms upward and the legs close to the body, exhibiting aposematic colors on the ventral region (Fig. 1). It remained in this position for about 3 minutes, afterwards slowly returning to normal position.

FIG. 1. Adult male *Ameerega flavopicta* exhibiting death-feigning behavior.

Deimatic behavior associated with parental care is known for this species (Toledo et al. 2004. Phyllomedusa 3[2]:145–147). However, this is the first reported case of death feigning in *A. flavopicta*. A voucher specimen is deposited at the Coleção Zoológica da Universidade Federal de Goiás (ZUFG 3031).

We thank Anglo American for financial and logistical support during this study and M. F. Felismino for correction of the English text. F. H. Oda was supported by a master's degree fellowship (2005–2006) from FUNAPE (Fundação de Apoio à Pesquisa – UFG).

***BOMBINA VARIEGATA PACHYPUS* (Apennine Yellow-bellied Toad). CANNIBALISTIC OOPHAGY.** *Bombina variegata pachypus* occurs throughout peninsular Italy (IUCN Red List 2010: Endangered). It is considered by some as a distinct species (*B. pachypus*; Canestrelli et al. 2006. Mol. Ecol. 15:3741–3754), although recent evidence suggests it is nested in the *B. variegata* clade (Hofman et al. 2007. Mol. Ecol. 16:2301–2316). As *B. pachypus*, it is listed as Endangered in the IUCN Red List (www.iucnredlist.org, assessed 2009). It has an extended breeding season (May–September), during which discrete spawning events alternate with non-breeding phases (Guarino et al. 1998. Ital. J. Zool. 65:335–342). Tadpoles are macrophagous and known to be at least partly carnivorous, although they feed mainly on algal

film (Bonacci et al. 2008. Zool. Anz. 247:47–54). Larval development mostly occurs in small, ephemeral water bodies. As in other *B. variegata* subspecies, the lower trophic availability and higher desiccation risks of shallower ponds represents a trade-off against the higher predatory pressure and slower tadpole development rates of colder, more permanent water bodies (Barandun and Reyer 1997. Amphibia-Reptilia 18:143–154).

On 31 July 2012, during surveys of a population of *B. v. pachypus* in Val Fontanabuona, Liguria, Italy (44.41666°N, 9.25°E, elev. 410 m), twelve tadpoles (Gosner stage 26–30) were observed to feed on a single mass of approx. 20 eggs. Tadpoles and eggs were located in a small (40 x 40 cm) rock pool near a mountain stream in argillite-shale substrate. Both were identified as *B. v. pachypus*, and no other amphibian species has ever been observed at the site during extensive surveys since 2009. In total, the pond hosted ca. 40 tadpoles in Gosner stage 26–30 and ca. 15 undergoing metamorphosis (Gosner stage 39–46). On previous occasions, we had recorded two separate spawning events in the pond in late May and mid-June, with a maximum number of ca. 60 tadpoles of various stages.

Cannibalistic oophagy has been reported for adults of *B. variegata*, but never for larval stages (Polis and Myers 1985. J. Herpetol. 19:99–107). Since 2009, we have monitored several populations of *B. v. pachypus* in the area, recording larval density and activity. However, this was the first instance of cannibalistic oophagy we observed. The small size of the water body and the high density of tadpoles, together with the co-occurrence of different cohorts from different spawning events, suggest late-stage tadpoles might accelerate their development by feeding on recently laid eggs with high protein contents. This might also represents a density-regulating factor for subsequent tadpole cohorts, diminishing the intra-cohort competition when water levels decrease later in the season.

Manuzio 14, 16143 Genova, Italy (e-mail: belfiore.fa@gmail.com).

***CHIROMANTIS DORIAE* (Doria's Asian Treefrog). PREDATION.** *Chiromantis doriae* occurs in Cambodia, China, India, Laos, Myanmar, Thailand, and Vietnam. It can be found in paddy fields, abandoned farmland and ponds in shrublands, and forests (Fei et al. 2010. Colored Atlas of Chinese Amphibians. Sichuan Publishing House of Science and Technology, China. 519 pp.). Here we present the first report of predation on *C. doriae* by a spider belonging to genus *Dolomedes* that is the first documented record of this frog species predated by invertebrates.

During a field survey in an abandoned fishpond near Yinggeling Nature Reserve (19.02407°N, 109.40511°E, WGS 84; elev. 320 m), Hainan Island, China, on 29 August 2012, at 2130 h, we observed that a male *C. doriae* (SVL ca. 2.5 cm) was held by a *Dolomedes* sp. with its mouthpart on a grass stalk 80 cm above the water. The frog was immobilized and not breathing. There was a wound on the back of the frog, part of the tissue was probably digested by the spider and the spinal cord was exposed (Fig. 1).

In other regions, frogs are common prey of spiders (Menin et al. 2005. Phyllomedusa 4:39–47). In this same pond, we also detected *Kurixalus bissaculus*, *Liuixalus hainanus*, *Microhyla butleri*, *Microhyla heymonsi*, and *Occidozyga martensii*; all are of similar size as *Chiromantis doriae*. Frogs may be an important prey item for *Dolomedes* sp., at least in the wet season.

***DENDROPSOPHUS NORANDINUS* (North Andean Treefrog). DIET.** *Dendropsophus norandinus* is an endemic Colombian treefrog occurring in the northeastern part of the Cordillera Central in the municipalities of Amalfi and Anorí (Department of Antioquia), between 1420 and 1950 m elev. (Rivera-Correa and Gutiérrez-Cárdenas 2012. Zootaxa 3486:50–62). Published information on the natural history of this species is limited to the description of habitat use and predation by the snake *Leptodeira septentrionalis* (Rivera-Correa and Gutiérrez-Cárdenas 2010, *op. cit.*); no information exists on its food habits. Herein we provide data on the stomach contents of 15 individuals (museum vouchers Museo de Herpetologia Universidad de Antioquia, Medellín, Colombia, MHUA-A 3824–3838) collected by PDAGC on 27–29 September 2003 between 2300 and 0100 h and on 12–13 November 2003 between 1400–1800 h, in the "Bosque La Forzosa" (6.980555°N, 75.135277°W, ca. 1700 m elev.), municipality of Anorí, Department of Antioquia.

Only 53% of the individuals had identifiable stomach contents (three males, two females, and three juveniles; MHUA-A 3824–3826, 3829, 3831, 3833–3835). Males ranged from 25.3–26.4 mm SVL (mean 25.93 ± 1.41), females from 33.1–35.1 mm SVL (mean 34.10 ± 0.57), and juveniles from 11.8–14.3 mm SVL (mean 13.33 ± 1.34). We identified each prey item to order or family as possible, and measured the length and width to nearest 0.1 mm

TABLE 1. Types of prey in the diet of *Dendropsophus norandinus* from the "Bosque La Forzosa," Anorí, Antioquia, Colombia. Volume in mm^3.

Prey	Number (%)	Volume (%)	Frequency of occurrence
Arachnida			
Acari	1 (8.3)	4.19 (3.49)	1
Undet.	1 (8.3)	10.47 (8.73)	1
Insecta			
Coleoptera			
Chrysomelidae	2 (16.7)	12.57 (10.48)	1
Hemiptera			
Cercopidae	2 (16.7)	65.97 (54.99)	1
Cicadellidae	1 (8.3)	1.57 (1.31)	1
Hymenoptera			
Formicidae	3 (25.0)	2.42 (2.02)	2
Lepidoptera			
Noctuidae	1 (8.3)	7.07 (5.89)	1
Orthoptera			
Gryllidae	1 (8.3)	15.71 (13.09)	1
TOTAL	12	119.97	

of each item using a manual caliper. We estimated prey volume using the formula for a prolate spheroid. The diet was comprised only of arthropods (six orders and six families; Table 1), without a marked numeric dominance of a single prey item. Volumetrically, froghoppers (Cercopidae) were the most important prey item, followed by the crickets (Gryllidae) and leaf beetles (Chrysomelidae). The adults ate all prey items, except the leaf beetles and all were represented by a single prey item (except Cercopidae). Chrysomelid beetles, were consumed only by the juveniles. These results may be explained by the tendency of larger individuals to incorporate larger prey into their diets (Hirai and Matsui 2002. J. Herpetol. 36:719–723; Valderrama-Vernaza et al. 2009. J. Herpetol. 43:114–123), and that each frog consumes fewer prey as the SVL increases (González-Duran et al. 2011. Herpetol. Rev. 42:583–584).

Reports on the diet of other *Dendropsophus* species (*D. ebraccatus*, *D. microcephalus*, *D. nanus*, *D. phlebodes*, *D. sanborni*) suggest that these frogs are generalists, eating various arthropods, principally insects (Jiménez and Bolaños 2012. Phyllomedusa 11:51–62; Macale et al. 2008. Herpetol. J. 18:49–58; Menin et al. 2005. Rev. Bras. Zool. 22:61–72; Muñoz-Guerrero et al. 2007. Caldasia 29:413–425; Peltzer and Lajmanovich 2000. Bol. Asoc. Herpetol. Esp. 11:71–73). The three most important prey found in *D. norandinus* were also found in *D. nanus* and *D. phlebodes*, but in these species dipterans, spiders, larval butterflies, cicadellids, and checkered beetles (Cleridae) accounted for the largest volume of prey items (Jiménez and Bolaños 2012, *op. cit.*; Macale et al. 2008, *op. cit.*; Menin et al. 2005, *op. cit.*).

We are grateful to C. Molina, J. C. Arredondo, P. C. Mejia., L. Bravo, W. Rios, and H. Ramírez for field assistance; A. L. Montoya helped identify prey items. V. Páez provided access to the collections. Universidad Nacional de Colombia sede Medellín (Grant DIME-030803682) and Universidad de Antioquia (Grant CODI-IN517CE) provided financial support. PDAGC and MRC receive Ph.D. grants from CAPES (bolsista da CAPES/CNPq – IEL Nacional - Brasil) and CNPq respectively.

***EUPEMPHIX NATTERERI* (Four-eyed Frog). PREDATION.** Snakes are well known to prey upon anurans (Michaud and Dixon 1989. Herpetol. Rev. 20:39–41). Toledo et al. (2007. J. Zool. 271:170–177) reported that approximately 45% of cases of predation of anurans were conducted by snakes. *Erythrolamprus poecilogyrus* is a widely distributed colubrid snake from South America (Dixon and Markezich 1992. Texas J. Sci. 44:131–166). Despite its terrestrial habits this species is often found in flooded areas and close to water bodies (Pinto and Fernandes 2004. Phyllomedusa 3[1]:9–14). Its diet consists of insects, fishes, amphibians, lizards, and rodents (Achaval and Olmos 2003. Anfíbios y Reptiles del Uruguay, 2nd ed. Impresora Graphis, Montevideo, Uruguay. 136 pp.). *Eupemphix nattereri* is a terrestrial, nocturnal anuran found in open areas after heavy rains (Uetanabaro et al. 2008. Field Guide to the Anurans of the South Pantanal and Surrounding Cerrados. Edit UFMS Campo Grande, MS).

On 24 Oct 2007 at 2205 h, along the margin of a tempory pond in the municipality of Miranda, Mato Grosso do Sul State, Brazil (20.083931°S, 56.613210°W; WGS84), we observed an attempted predation by an adult *E. poecilogyrus* on *E. nattereri*. During 20 minutes, we observed an *E. poecilogyrus* trying to swallow an *E. nattreri* headfirst, which filled its lungs with air, thus hindering ingestion. After some time the *E. nattereri* escaped, possibly due to the poisoning of the snake through contact with secretions from glands scattered on the frog's body. Species of the genus *Eupemphix* and *Physalaemus* are known to have physalaemins in the skin, peptides that act as a hypotensive and stimulates smooth muscles in vertebrates (Erspamer et al. 1964. Experientia XX/9:489–490). Sazima and Caramaschi (1986. Rev. Biol. 13:91–101) reported that under a perch of a Barn Owl (*Tyto alba*), four dead but intact specimens of *E. nattereri* were found together with regurgitated pellets, indicating a possible toxic effect of the skin secretions on the bird. In an experiment, the same authors, offered an *E. nattereri* to a *Nasua nasua*, which placed the frog in its mouth but then immediately rejected it. Rodrigues and Filho (2004. Herpetol. Rev. 35:160–161) also described the unsuccessful predation attempt by *Leptodactylus latrans*, which regurgitated the prey. The specimens reported in this note were identified in the field and soon after released.

We believe that this failed predation was due to the action of toxins from the skin of *E. nattereri*, showing how the chemical mechanism plays an important role in the species defense against potential predators.

We are grateful to the Conselho Nacional de Desenvolvimento Científico e Tecnológico (Process n° 470148/2006-3) for financial support, and to Fazenda San Francisco for logistical support.

cias Biológicas e da Saúde, Universidade Federal de Mato Grosso do Sul, Cep 79070-900 Campo Grande, MS, Brazil; **LILIANA PIATTI**, Centro de Ciências Biológicas e da Saúde, Universidade Federal de Mato Grosso do Sul, Cep 79070-900 Campo Grande, MS, Brazil (e-mail: lilianapiatti@gmail.com); **FERNANDO IBANEZ MARTINS**, Centro de Ciências Biológicas e da Saúde, Universidade Federal de Mato Grosso do Sul, Cep 79070-900 Campo Grande, MS, Brazil (e-mail: fimquelonio@hotmail.com).

***HYLA GRATIOSA* (Barking Tree Frog). ALGAL HARVEST.** Although most tadpoles are not herbivores in the strict sense, they do harvest large amounts of periphyton to gain access to other nutritional material. Experiments involving the feeding behaviors of tadpoles usually focus on the tadpole's response, and the efficiency of the algal harvest is not shown.

We submerged a number of plastic coverslips about 10 cm below the surface of a permanent pond for two weeks to allow the growth of a layer of periphyton. We allowed tadpoles of *Hyla gratiosa* (ca. 58 mm TL and Gosner stage 33) to feed from these periphyton mats before the coverslips were frozen in liquid nitrogen, lyophilized, and sputter-coated for scanning microscopy.

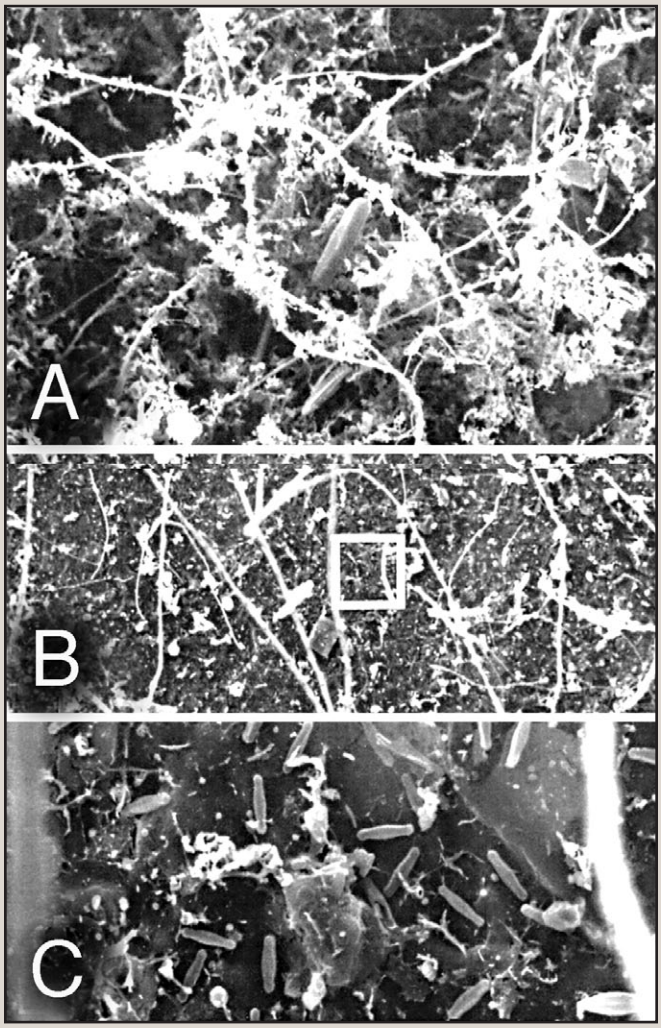

FIG. 1. **A)** A scanning microscopy image of an intact periphyton mat grown on glass in a native pond; **B)** part of the same area after being fed upon by a tadpole of *Hyla gratiosa*; and **C)** an electronic enlargement of part of the area within the white rectangle in frame B.

The coverslips initially had a dense canopy of filamentous algae, fungi, diatoms, and other algae (0.4 mm tall after lyophilization Fig. 1A). The feeding tadpoles removed the overstory (Fig. 1B) but left adnate diatoms and other small algae near the substrate (Fig. 1C, part of area of white square in Fig. 1B). After the tadpoles fed it appeared that most of the material had been removed, but about 41% (0.85 vs. 0.50 mg/cm²) of the chl *a* remained; that is, much of the material removed was not chlorophyllic and much of the chlorophyll was contained in small organisms that were closely attached at the base of the periphyton layer.

Occasional isolated bites taken from the surface of the periphyton mat did not penetrate the total algal canopy; algal filaments were cut and not merely pulled from the mass. Usually the tadpole attacked at an edge and systematically harvested the entire mat. In one case, the 4.7 cm² surface was grazed during three feeding bouts within 39 min. Single feeding bouts ranged from 3.0–57.0 (30.1 ± 4.0) sec, and resting bouts ranged from 4.0–653.0 (134.4 ± 47.1) sec. In one case, five short feeding bouts that totaled about 1.5 min were followed by a rest period of 7 min. Filamentous material could be seen being manipulated in the buccopharynx of this relatively translucent tadpole during resting bouts. Apparently when a critical amount was harvested relative to an unknown limitation of the buccopharyngeal apparatus, the tadpole rested quietly. These observations suggest that the amount of material harvested differed in some way among bouts, all of the material was not removed from the buccopharynx during a given rest, feeding on bulky material interfered with respiratory currents, or the tadpole fatigued. In any case, the feeding mechanics of the tadpole did not form a slurry of small particles.

CINDY L. TAYLOR, Department of Biological Science, Austin Peay State University, Clarksville, Tennessee 37044, USA (e-mail: taylorc@apsu.edu); **RONALD ALTIG**, Department of Biological Sciences, Mississippi State University, Mississippi State, Mississippi 39762, USA (e-mail: raltig@biology.msstate.edu).

***ISCHNOCNEMA BILINEATA* (Two-lined Robber Frog). REPRODUCTION.** *Ischnocnema bilineata* is a small frog classified as "little concern" by IUCN due to its relatively wide distribution in the Atlantic Forest of the eastern State of Bahia, its tolerance to habitat disturbance, and its large population size (Junca and Pimenta 2004. *In* IUCN 2012. IUCN Red List of Threatened Species. Ver. 2012.1 http://www.iucnredlist.org. Accessed 07 August 2012). However, information regarding this species is limited. We collected a gravid female (UFBA 011447, 30.4 mm SVL) in a pitfall trap in Estação Ecológica Serra do Timbó (13.108083°S, 39.670583°W), municipality of Amargosa, State of Bahia, Brazil. We dissected the female and found 10 unfertilized eggs which averaged 3.07 ± 0.13 mm (mean ± SD) with a volume of 6.42 ± 0.27 mm³. The relatively large size of the eggs and their small number is compatible with that observed for species with direct development (Salthe and Duellman 1973. *In* J. L.Vial [ed.], Evolutionary Biology of the Anurans: Contemporary Research on Major Problems, pp. 229–249. Univ. Missouri Press, Columbia).

We thank Maria Cunha for the English translation, INOMEP (Integrando Níveis de Organização em Modelos Ecológicos Preditivos) for financial and logistical support, and ICMBio/RAN for the collecting permit, number 12023-4.

***LEPTODACTYLUS FUSCUS* (Rufous Frog) and *ELACHISTOCLEIS OVALIS* (Oval Frog). REPRODUCTIVE BEHAVIOR.** *Leptodactylus fuscus* and *Elachistocleis ovalis* are tropical, terrestrial frog species that inhabit rainforests and forest edge, as well as grasslands and shrublands. These species are known from the Pacific lowlands of central Panama, throughout South America east of the Andes, to southern Brazil, Bolivia, and northern Argentina. In Colombia they are found in the Caribbean region, inter-Andean valleys, and the Orinoquia region. *Leptodactylus fuscus* is a relatively small species (43–70 mm SVL) that is closely associated with open savannah, streams, and creeks where it breeds in permanent or temporary ponds. *Elachistocleis ovalis* is a considerably smaller species (39–40 mm SVL), and is linked to open flooded areas and agricultural land where it seeks refuge underground and breeds (Medina-Rangel et al. 2011. Anfibios y Reptiles de los Alrededores del Complejo Cenagoso de Zapatosa, Departamento del Cesar, Colombia. Instituto de Ciencias Naturales, Universidad Nacional de Colombia-CORPOCESAR, Bogotá D.C. 105 pp.; Cochran and Goin 1970. Frogs of Colombia. U.S. Natl. Mus. [288]:1–655).

Reports of interspecific amplexus among frogs are relatively common at different locations and latitudes (Pearl et al. 2004. Am. Midl. Nat. 154:126–134; Streicher et al. 2010. Herpetol. Rev. 41:208; Grogan and Grogan 2011. Herpetol. Rev. 42:89–90; Manzano and Corzas 2011. Herpetol. Rev. 42:84; Turner 2012. Herpetol. Rev. 43:123). However, amplexus in species that are morphologically very different is not often reported. Mollov et al. (2010. Biharean Biol. 4[2]:121–125) suggest that amplexus is abnormal if the amplexus is between a live frog and a dead or morphologically very different species. Herein I report one such example of amplexus between *E. ovalis* and *L. fuscus*, despite the large differences in size and morphology.

At 2000 h on 3 June 2010, I observed a male *E. ovalis* in amplexus with an adult *L. fuscus* of undetermined sex. Weather conditions were cloudy with light rain during the afternoon. The pair was encountered immobile within the tree-lined savanna at the edge of a temporary pool at the edge of a village (176 m elev.) near Vereda La Poyata, township of Mani, department Casanare, Colombia (72.149114°E, 4.44453°N; Bogotá WGS 84). The male *E. ovalis* had a firm grasp around the armpits of the *L. fuscus* (axillary amplexus). The frogs were observed at close range for a period of ca. 10 min. during which time there was no movement. Although the pair was briefly manipulated, they remained in amplexus as they were photographed (Fig. 1). One possible explanation for this amplexus, may be due to the confusion of chemical signals as stated by Mollov et al. (2010, *op. cit.*). The timing of this observation coincided with the start of the breeding season of both species in the local area.

FIG. 1. Male *Elachistocleis ovalis* in amplexus with an adult *Leptodactylus fuscus* of undetermined sex.

***LEPTODACTYLUS GRACILIS* (Dumeril's Striped Frog). ALBINO TADPOLE.** In recent years the number of reports on albinism in anurans has notably increased. However, the observation of this anomaly in nature remains a rare event (Toledo et al. 2011. Herpetol. Notes 4:145–146). In Uruguay, there is only one report of albinism in amphibians, that being in the larvae of *Melanophryniscus montevidensis* (Maneyro and Achaval 2004. Herpetol. Rev. 35:261).

Although there is a report of albinism in Leptodactylidae (Rodriguez and De Oliveira Filho 2004. Herpetol. Rev. 35:373), this is the first report of an albino *Leptodactylus gracilis* tadpole. The specimen was found on 24 April 2012 in the "Barra de Laguna de Rocha," Rocha county, Uruguay (34.667027°S, 54.233694°W) in a temporary pond (0.60 m max depth, ca. 300 m^2). This geographical region belongs to a Protected Area (Paisaje Protegido Laguna de Rocha). The albino tadpole was caught at 2110 h together with 20 *Odontophrynus* sp. larvae. Air temperature was 14.0°C, water temperature 14.2°C, and pH 6.58. The habitat surrounding the water body was mainly composed of grasses and *Eryngium pandanifolium*. When collected the tadpole was at Gosner stage 40 (Fig. 1a) (Gosner 1960. Herpetologica 16:183–190). The specimen was maintained in captivity for two weeks, although it died as a juvenile after completing metamorphosis (Fig. 1b). The individual was accessioned into the Vertebrate Collection of the Faculty of Sciences (ZVCB 22737).

The rarity of albino specimens may be due to the low frequency of occurrence, low breeding success, or differential mortality (Childs 1953. Evolution 7:228–233). This mortality could be due to increased predation because of the ease of detection in nature (Childs 1953, *op. cit.*), or some intrinsic physiological factors (Toledo et al. 2011, *op. cit.*). To obtain more information about the mortality of albino individuals more records and experimental work is necessary.

Our fieldwork was partially supported by the Agencia Nacional de Investigación e Inovación (Proyecto ANII FCE 2009-1-2514).

***LEPTODACTYLUS MELANONOTUS* (Sabinal Frog). ENDOPARASITISM.** *Leptodactylus melanonotus* is a small frog ranging from northwestern Mexico to Central America and Ecuador, in arid and wet mountain woodlands. The species is nocturnal, semiaquatic, insectivorous, oviparous, and can persist in anthropogenic disrupted areas; it is indeed an indicator of impacted areas (Ramírez-Bautista and García 2002. *In* Noguera et al. [eds.], Historia Natural de Chamela, pp. 251–264. Universidad Nacional Autónoma de México). *Leptodactylus melanonotus* is listed in the category of Least Concern with populations considered "stable" (Solís et al. 2010. *In* IUCN Red List of Threatened Species. Ver. 2012.1, <www.iucnredlist.org>. Accessed 28 June 2012).

During recent work on the metazoan parasites of *L. melanonotus* in the Chamela-Cuixmala Biosphere Reserve in Jalisco, west-central Mexico, 20 specimens were examined. One frog (prevalence 5%) from Chamela Creek (19.52738°N, 105.06994°W) was parasitized with 10 chiggers *Hannemania hylae* (Leeuwenhoekiidae). Chiggers were found on the ventral skin, into the subdermal layer of trunk and hind legs (thighs) of the host. The term "chiggers" refers to larvae of parasitic mites of the families Trombiculidae and Leeuwenhoekiidae, associated with vertebrates. Chiggers in the genus *Hannemania* are subdermal parasites restricted to amphibians. Voucher specimens are housed at the Colección Nacional de Ácaros, Universidad Nacional Autónoma de México, Instituto de Biología, México, D.F., with accession numbers CNAC007098–007102.

This is the first record of *H. hylae* on *L. melanonotus*. *Hannemania hylae* ranges from the southwestern USA to Argentina, and was previously reported parasitizing *Hyla arenicolor*, *Pseudacris cadaverina,* and *Eleutherodactylus guttilatus* from several localities in the USA (Jung et al. 2001. Herpetol. Rev. 32:33–34; Loomis and Welbourn 1969. Bull. So. California Acad. Sci. 68:160–168). The species has been reported from *P. cadaverina*, *Lithobates berlandieri, Eleutherodactylus* sp., *E. longipes*, *Lithobates* sp., *Scaphiopus couchii*, and *Incilius mazatlanensis* in Mexico (Espino del Castillo et al. 2011. Int. J. Acarol. 37:427–440; Goldberg et al. 2002. Herpetol. Rev. 33:301–302; Hoffmann 1969. Rev. Latinoam. Microbiol. Parasitol. 11:209–216; Hoffmann and López-Campos 2000. Biodiversidad de los Ácaros en México. CONABIO, UNAM, México 230 pp.; Loomis and Welbourn 1969, *op. cit.*), and is also known to infest *Hypsiboas curupi* from Argentina (Alzuet and Mauri 1985 [1987]. Rev. Soc. Entomol. Argentina 44:111–116).

Frogs were collected under permit FAUT-0250 issued to Gerardo Suzán and will be deposited at Colección Herpetológica, Estación de Biología Chamela.

***OSTEOPILUS SEPTENTRIONALIS* (Cuban Treefrog). PREDATION.** The introduced Cuban Treefrog occurs throughout most of peninsula Florida and has established populations as far north as Nassau Co. at the Florida-Georgia state line (Krysko et al. 2011. Atlas of Amphibians and Reptiles in Florida. Final report, Florida Fish and Wildl. Cons. Comm., Tallahassee. 524 pp.). Known predators of this frog in North America include several species of snakes and birds, as well as conspecifics (Meshaka 2001. The Cuban Treefrog in Florida, Univ. Press of Florida, Gainesville. 191 pp.). No invertebrate predators have been reported. On 25 September 2010, we observed predation of a young adult *O. septentrionalis* by a giant water bug, *Lethocerus americanus* (Belostomatidae), at the edge of a small, vegetated pond on the Santa Fe College campus, Gainesville, Alachua Co., Florida (29.704167°N, 82.44333°W; WGS 84). The bug held the frog with its right front leg inserted into the frog's left axilla and the left front leg placed around the front of its snout (Fig. 1). Its beak was inserted behind the left eye. The frog was dead by the time it was observed. Giant water bugs in the genus *Lethocerus* are well-known predators of adult and larval anurans (Graham et al. 2011. Herpetol. Rev. 42:84; Hinshaw and Sullivan 1990. J. Herpetol. 24:196–197; Toledo 2005. Herpetol. Rev. 36:395–400). This bug obviously found the frog palatable because it was not deterred by the sticky and noxious skin secretions that cause nasal irritation in humans (Meshaka 2001, *op. cit.*; JCM, pers. obs.). This is the first report of giant water bug predation on adults of the introduced Cuban Treefrog.

Matt Kail aided in the field observation.

***PELTOPHRYNE LEMUR* (Puerto Rican Crested Toad). REFUGIA and DEFENSIVE BEHAVIOR.** Very few natural history observations have been documented for *Peltophryne lemur* due to its rarity and semi-fossorial nature. *Peltophryne lemur* habitat in Puerto Rico is comprised primarily of arid to semi-arid areas containing an abundance of Karst limestone and well-drained soils at low elevations (< 200 m above sea level) (Lee 1992. USDI Fish Wildl. Serv., Caribbean Field Office, Boquerón, Puerto Rico). However, the species is also known to inhabit river beds, grassy fields, and moist forests (Garcia-Diaz 1967. Stahlia [10]:1–6; Moreno 1985. Unpubl. report, Puerto Rican Dept. Natural Resources, San Juan). Outside of breeding events, *P. lemur* has been observed on, under, or in holes and crevices within limestone rock, where it appears to seek protection from predators and refuge from the heat (Schmidt 1928. New York Acad. Sci.

FIG. 1. Newly metamorphosed *Peltophryne lemur* scale steep limestone in search of holes and crevices for shelter.

FIG. 2. Male *Peltophryne lemur* utilizing an abandoned bird nest in vertical dirt bank.

FIG. 3. An empty tarantula burrow under a mango tree serves as refuge for a male *Peltophryne lemur*.

[10]:1–160; Johnson 1999. Endangered Spec. Bull. 24[3]:8–9; Matos-Torres 2006. M.S. Thesis. Univ. Puerto Rico, Mayagüez; pers. obs.). When disturbed, this toad often remains still and relies on cryptic camouflage to avoid detection (Schmidt 1928, *op. cit.*; pers. obs.). It is typical for biologists monitoring *P. lemur* to find them in limestone rock crevices, yet little has been documented regarding specific use of these microhabitats. During a radio telemetry study in the Guánica State Forest in 1990, it was noted that toads used rock holes and crevasses for refuge during the day and would climb vertical rock faces to reach shelter in the limestone at least 45 cm above the ground (Lentini 2002. PRCT SSP Husbandry Manual. Toronto Zoo). Also in Guánica, a habitat characterization study concluded that 53% of observed toads utilized rocky areas with cacti (limestone scrub) the majority of the time compared to other habitat types (scrubland, semi-evergreen forest, and evergreen forest). It was surmised during this study that the use of limestone areas linked to subterranean water and cave systems is an important adaptive factor for this species since the toads have been previously found in underground caves (Matos-Torres 2006, *op. cit.*).

Herein we document additional refugia sites, verify the suspected used of the head for defense (Rivero et al. 1980. Carib. J. Sci. 15:33–40), and relay further behavioral observations of *P. lemur* in Puerto Rico. On 2 Nov 2005, we observed newly metamorphosed toads at 0928 h climbing steep limestone rock 1.2 m above ground in search of refugia holes in Guánica (Fig. 1). At 2130 h on 12 May 2010 at a reintroduction site near Arecibo, we found a male *P. lemur* protruding out of a hole on a steep vertical dirt bank ca. 2.13 m above the ground (Fig. 2). The hole was most likely excavated and abandoned by a *Todus mexicanus,* an endemic species of bird that utilizes hillsides in the area to create nesting sites. At 2102 h on 16 May 2012, an adult male toad was observed in a presumed tarantula (*Cyrtopholis portoricae*) burrow (Fig. 3) in a mango plantation near Punta Ventana. Also in Ventana, near an ephemeral pond, between 1845 h and 2030 h on 16 June 2012, 16 juvenile and adult toads (4.0–6.9 cm SVL) were found in limestone holes and crevices. During this event, two juvenile toads were sitting 4.0 cm apart within a single horizontal crack measuring 3 cm tall x 15 cm wide x 7 cm deep. The entrances of the other holes utilized by toads ranged from 1.5 to 4.5 cm wide and 2.0 to 4.5 cm tall. All of the toads inside of the holes were sitting with their heads facing outward from the side of large boulders. Depths of the holes from the rock surface to the head of each toad varied from 3.5 to 9.0 cm. Upon our approach, toads pulled backward, deeper into their holes, and tucked their lower jaw to the chest so that the bony top of the head formed a shield blocking the rest of the body. Several toads were also observed pulling their closed eyes deep into their sockets for additional protection. The vertical distance from the holes to the ground at Ventana ranged from 30.48 cm to 1.52 m. We have also observed individual crested toads utilizing the same holes as permanent refuge. On 13 June 2012 during the evening, two adult males were found in separate holes on the same vertical dirt bank as previously reported in May 2010. Passive Integrated

Transponder (PIT) tags were inserted into the toads, which were found in their respective holes five days later at 1220 h. Later that day at 2120 h, the toads were found foraging just outside of their holes under the cover of darkness. The hole openings were 2.5 cm wide × 2.0 cm tall and 3.4 cm wide × 3.0 cm tall and were 1.82 m and 1.52 m above the ground, respectively.

These observations were made while conducting research with permission of the USFWS, PRDNER, and private landowners. We thank them for their continued support.

***PHYLLOMEDUSA CAMBA*. DEFENSIVE BEHAVIOR.** *Phyllomedusa camba* is a species in the *P. tarsius* group distributed in Bolivia, Peru, and Brazil in the states of Amazonas, Acre, Mato Grosso, and Rondonia (Frost 2011. Amph. Species of the World; Rodrigues et al. 2011. Checklist [2]:397–399). On 03 November 2011, we observed the defensive behavior of an adult male *P. camba* at the Terra Indígena do Zoró, Mato Grosso, Brazil (10.31780°S, 60.51561°W, SAD69; elev. 179 m). When disturbed, the individual began secreating a milky venom from the doral glands (Fig. 1A), raised the body (Fig. 1B), and began making lateral movements as if to attack the intruder (Fig. 1C).

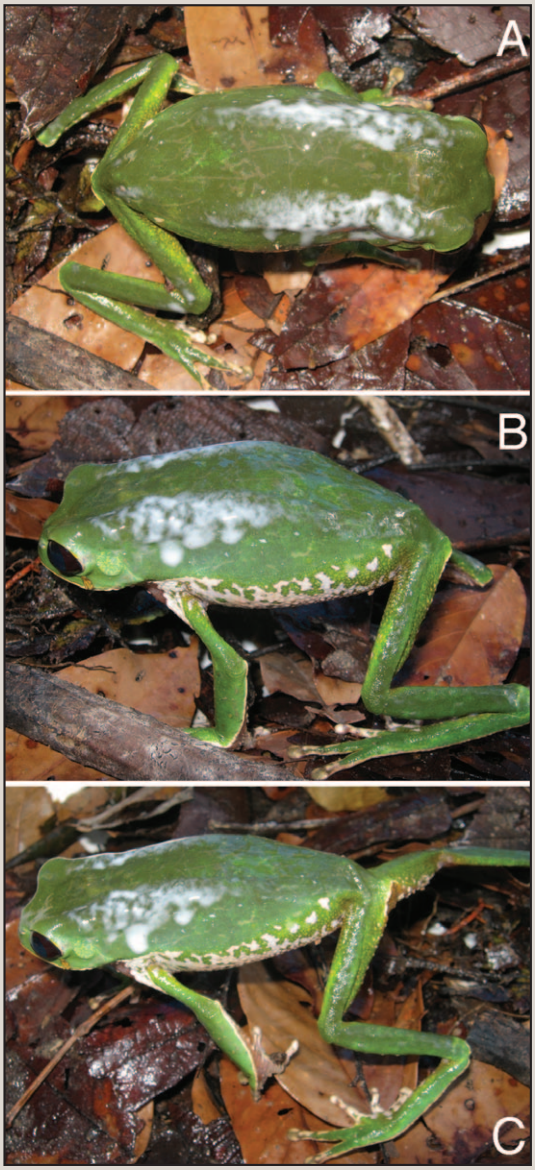

FIG. 1. *Phyllomedusa camba* from Terra Indígena do Zoró, Mato Grosso, Brazil showing defensive behavior. A) Secreting milky toxins from the dorsal glands; B) raising the body; C) defensive movements towards the attacker.

***RANA DRAYTONII* (California Red-legged Frog). CANNIBALISM.** *Rana draytonii* has been the subject of numerous research reports and notes documenting predation. Specifically, several predators have been reported for *R. draytonii*, including Great Blue Heron (*Ardea herodias*) (Fellers and Wood 2004. Herpetol. Rev 35:163), Loggerhead Shrike (*Lanius ludovicianus*) (Alvarez 2005. Ecol. Restor. 23:66–67), American Bullfrog (*Liothobates catesbeianus*) (Jennings and Cook 2001. Herpetol. Rev. 33:182–183), and several others (US Fish and Wildlife Service 2002. Recovery Plan for the California red-legged frog [*Rana aurora draytonii*]. Portland, Oregon). Herein I report on mortality from the cannibalistic behavior of two life stages of this federally threatened species.

While monitoring a stock pond in eastern Contra Costa Co., California, USA (37.81708°N, 121.78768°W; elev. 601 m), I observed a larval *R. draytonii* appearing to feed on an object floating at the surface. Larvae of *R. draytonii* are typically observed feeding within vegetation, likely filter-feeding on algae, protozoans, and phytoplankton from the surfaces and substrate within the pond (Stebbins and Cohen 1995. A Natural History of Amphibians. Princeton Univ. Press, Princeton, New Jersey. 316 pp.). In this instance, upon close inspection with binoculars, I was able to determine that the larva engaged in feeding was *R. draytonii* and that the object on which it fed was a second *R. draytonii* larva. It appeared that the larva being consumed was still alive, although it moved very little. I observed that the predating larva appeared to feed by scraping the surface of its *R. draytonii* prey. This behavior continued for 12 minutes during my observations.

During the same day, and at the same site, I observed approximately 245 post-metamorphic *R. draytonii*. While conducting individual counts I noted two distinct size cohorts. This is a typical observation at stock ponds in this general area, and likely reflects the metamorphosis of current-year larvae and larger *R. draytonii* metamorphosing after overwintering as larvae (Fellers et al. 2001. Herpetol. Rev. 32:156–157). On 26 occasions I observed the larger-size cohort (approx. 50.8 mm), attempting to feed upon the smaller size cohort (approx. 25.4 mm) (Fig. 2). Feeding attempts typically started with the larger animal orienting toward the smaller. The larger frog remained motionless until the small frog moved, at which time the larger frog leapt directly at and onto the smaller with mouth agape. In 25 of the 26 observations of this activity, the smaller frog escaped. On one attempt, the larger frog was able to grasp and ultimately consume the smaller.

These observations suggest that *R. draytonii* of two life stages number among the seasonally abundant resources utilized by

FIG. 1. A larval *Rana draytonii* cannibalizing a conspecific at the surface of a stock pond.

FIG. 2. Two size cohorts (frog on right is approx. 25 mm; frog on left is approx. 50 mm) of *Rana draytonii*, with the larger cannibalizing the smaller shortly after the photo was taken.

both pre- and post-metamorphic *R. draytonii* and are taken by cannibalistic feeding. This cannibalism likely is opportunistic and provides a seasonally abundant source of protein for larvae and post-metamorphic frogs.

These observations contribute to the greater understanding of the natural history and population dynamics within occupied breeding habitat for *R. draytonii*. Cannibalism witnessed in this species is likely common among many anurans, but may confound attempts to increase populations of this rare species.

JEFF A. ALVAREZ, The Wildlife Project, PO Box 579805, Modesto, California 95357, USA; e-mail: jeff@thewildlifeproject.com.

***RANA DRAYTONII* (California Red-legged Frog). ASSOCIATION WITH BEAVER.** A number of new observations are being reported on microhabitat use by California Red-legged Frogs. Among these, Cook (1997. MS thesis, Sonoma State Univ., Rohnert Park, California. 23 pp.) reported on the use of microhabitat in a freshwater marsh by this species; Alvarez (2004. Herpetol. Rev. 35:85–86) documented the use of desiccation cracks in the bottoms of dry ponds by *R. draytonii* seeking shelter from extreme climatic conditions, and Alvarez et al. (*in press*. Amphibian Conservation and Biology) detailed the microhabitat use by ovipositing *R. draytonii* at several aquatic breeding habitats. Nonetheless, many natural history details related to this species remain unknown or unreported, and land managers continue to use scant information to make management decisions in habitat occupied by *R. draytonii*. This potentially creates conditions under which this federally listed species may be harmed or killed during land management activities. Here we report the use of dams and burrows (bank-lodges) constructed by beaver (*Castor canadensis*) as refugia for the *R. draytonii*.

In Spring 2000, it was discovered that beaver naturally colonized the upper portion of Kellogg Creek, downstream from Los Vaqueros Reservoir in Contra Costa Co., California, USA. This colonization was considered potentially damaging to mitigation developed for the construction of the reservoir, and catalyzed the design and implementation of a program to indirectly control the beavers through the removal of at least 24 beaver dams.

Two monitoring biologists were posted on-site during each dam removal to document any "take" of *R. draytonii*. Dams were removed with the aid of a backhoe equipped with a thumb. Twigs, branches, logs, and mud were grasped and pulled from the creek bed, and material was placed on the upper bank. Biologists maintained positions downstream of the dam and collected *R. draytonii* that were in harm's way from debris or inundation (Fig. 1). Collected frogs were released unharmed within the creek channel after each dam was removed.

During removal of the 24 beaver dams, 60 adult and subadult *R. draytonii* were collected and subsequently returned to the creek. Four *R. draytonii* larvae were also detected when a large portion of one beaver dam was removed and stranded the tadpoles in the previously inundated areas.

Over subsequent months, post-removal surveys were conducted along Kellogg Creek at various times to determine if beavers had restored their dams and if *R. draytonii* and other species were present. On one occasion, *R. draytonii* were observed utilizing a previously inundated burrow of a bank-lodge dug into the bank of Kellogg Creek. This burrow afforded refuge not only to the beavers and the *R. draytonii*, but also to Western Pond Tturtles (*Actinemys marmorata*), as observed during previous management actions (Alvarez 2006. Herpetol. Rev. 37:339).

It is clear that the infrastructure—both dams and burrows associated with bank-lodges—resulting from beaver activity provides refuge microhabitat for *R. draytonii*. Beaver-dammed water bodies also provide breeding habitat for *R. draytonii* adults and rearing habitat for tadpoles. These sites should be treated as critical to the survival of local populations of this species;

FIG. 1. Two adult *Rana draytonii* well-hidden within a beaver dam that was being removed along Kellogg Creek, Contra Costa Co., California.

removal of beavers or their dams within the range of *R. draytonii*, although potentially beneficial under certain circumstances, is likely to temporarily or permanently affect habitat suitability for this federally threatened species. Such removals should be avoided to the greatest extent possible.

Considering that beavers are native to the Central Valley of California and some streamcourses in surrounding foothills (Grinnell et al. 1937. Fur-bearing Mammals of California: Their Natural History, Systematics, and Relations to Man. Univ. of California Press, Berkeley. 777 pp.), beavers and *R. draytonii* likely co-evolved over much of the range of both species. Careful consideration should be made before controlling beavers within the range of this rare anuran species.

FOSTER**, The Wildlife Project, PO Box 579805, Modesto, California 95357, USA (e-mail: aspetree@yahoo.com).

***RANA LUTEIVENTRIS* (Columbia Spotted Frog). MAXIMUM SIZE.** Similar to other species in the *Rana boylii* group (Hillis and Wilcox 2005. Mol. Phylogenet. Evol. 34:299–314), *Rana luteiventris* is size-dimorphic in favor of females (Davis and Verrell 2005. Can. J. Zool. 83:702–711; Reaser 2000. Can. J. Zool. 1158–1167; Turner 1960. Ecol. Monogr. 30:251–278), so females reach the body-size maximum. Bull (2005. Ecology of the Columbia Spotted Frog in Northeastern Oregon. USDA, Forest Service, PNW-GTR-640. 45 pp.) reported the maximum body size for *R. luteiventris*, a 100 mm SVL female. Here, we augment that maximum.

While examining western North American ranid frogs for misidentifications at the Charles R. Conner Museum (CRCM), Washington State University (WSU), Pullman, Washington, we noted an unusually large female *R. luteiventris* (CRCM 42-34; Fig. 1). Conveniently preserved flat, this female measured 127 mm SVL. The specimen's tags and the CRCM catalog give the collection locality as simply Pullman, Whitman County, Washington (~46°73'N, 117°17'W, WGS 84; elev. ~750 m). However, the catalog also reveals that Roy D. Shenefelt, curator of the entomology collection at WSU (then Washington State College) around that time, collected this animal on 26 March 1942. No further details are available for this specimen, but the catalog provides locality modifiers for the two other vertebrates collected by Shenefelt, so the Pullman locality likely means Pullman proper rather than somewhere in the vicinity.

FIG. 1. Large female *Rana luteiventris* (CRCM 42-34) collected at Pullman, Washington, USA on 26 March 1942.

Three aspects of this observation merit comment. Recent phylogenetic work on *R. luteiventris* has revealed deep genetic subdivisions that may warrant taxonomic recognition (Funk et al. 2008. Mol. Phylogenet. Evol. 49:198–210). Based on locality, our large *R. luteiventris* falls within the area of what Funk et al. (2008, *op. cit.*) label as the Northern clade, which extends from southeastern Oregon to the Yukon Territory, Canada. Maximum sizes reported for *R. luteiventris* attributable to the remaining two clades of Funk et al. (2008, *op. cit.*) differ substantially (79 mm SVL for the Utah clade: Morris and Tanner 1969. Great Basin Nat. 29:45–81; and 90 mm SVL for the Great Basin clade: Reaser 2000, *op. cit.*), but whether variation among clades reflects any phylogenetic signal is unclear. Second, among native ranid frogs in western North America, the size of this female is exceeded only by *R. draytonii*, for which the maximum is 138 mm SVL (Hayes and Miyamoto 1984. Copeia 1984:1018–1022). Lastly, given that shrinkage is a typical artifact of long-term preservation (Deichmann et al. 2009. Phyllomedusa 8:51–58), our measurement of this 70-year-old specimen likely underestimates its size in life.

Richard Zack generously provided information on R. Shenefelt. A USFWS Competitive State Wildlife Grant (CFDA# 15.634) supported the work of MPH.

Conner Museum, School of Biological Sciences, Washingon State University, Pullman, Washington 99164-4236, USA (e-mail: connermuseum@wsu.edu).

***RANA SYLVATICA* (Wood Frog). LEUCISM.** On 2 June 2012 a single leucistic *Rana sylvatica* was captured by Campbell Schneider in a pond in Vanderhoof, British Columbia, Canada (54.026022°N, 124.049758°W). Luce and Moriarty (1999. Herpetol. Rev. 30:94)

FIG. 1. Leucistic *Rana sylvatica*, British Columbia, Canada.

reported the first record of an albino, however, to the best of our knowledge this is the first record of leucism reported for this species. The leucistic individual was transported to the University of Northern British Columbia for photographs and measurement (2.8 mm SVL, 1.55 g). After analysis, the frog was returned to its pond of origin. The specimen was ivory yellow to orange and pinkish on the limbs, but the eyes retained their color and some dark flecks could be seen on the face (Fig. 1). Pigmentation present in the eyes is a key diagnostic that distinguishes leucism from albinism. However, the frog's viscera were also darkly pigmented and could be seen through the dermis.

MARK THOMPSON (e-mail: mark.thompson@unbc.ca) and **ROY V. REA** (e-mail: reav@unbc.ca), Ecosystem Science and Management Program, University of Northern British Columbia, 3333 University Way, Prince George, British Columbia, V2N 4Z9, Canada.

RHACOPHORUS FEAE **(Thao Whipping Frog). HABITAT.** *Rhacophorus feae* is a poorly known, large-bodied rhacophorid from Asia. During amphibian and reptile surveys at high-elevations in Pu Hoat Proposed Nature Reserve, Que Phong District, Nghe An Province, Vietnam (19.66°N, 104.79°E, ca. 1300 m elev.), we uncovered an adult female *R. feae* in a terrestrial shelter site. The individual was discovered at 1550 h on 14 April 2011 while surveyors were raking leaf litter 15 m from a pond, and was covered by a 3-cm-thick layer of litter. The temperature and relative humidity at the time were 18.6°C and 100%, respectively. When uncovered, the frog displayed the defense posture previously documented for the species (Le and Rowley 2010. Herpetol. Rev. 41:342). Our discovery of *R. feae* in a terrestrial shelter site was unexpected for a tree frog that was thought to be arboreal. However, terrestrial retreat sites have been recorded previously in *Rhacophorus* (for the more terrestrial species *R. schlegelii*; Ihara 1999. Japan. J. Herpetol. 18:39–44) and in arboreal treefrogs in the family Hylidae (Rowley and Alford 2007. Dis. Aquat. Org. 77:1–9).

FIG. 1. *Rhacophorus feae* uncovered in diurnal shelter site under leaf litter, Nghe An Province, Vietnam.

ROWLEY**, Australian Museum, 6 College St, Sydney, NSW, 2010, Australia (e-mail: jodi.rowley@austmus.gov.au); **HOANG XUAN QUANG**, Department of Zoology, Vinh University, 182 Le Duan St, Vinh City, Nghe An Province, Vietnam.

RHACOPHORUS VIRIDIS VIRIDIS **(Okinawa Green Tree Frog). PREDATION.** Anuran amphibians are vulnerable to various predators at all stages of their life history (Wells 2007. The Ecology and Behavior of Amphibians. Univ. Chicago Press, Chicago, Illinois. 1148 pp.). Spiders seem to be the most important invertebrate predators of anurans (Toledo 2005. Herpetol. Rev. 36:395–400), although few reports have been published on Asian species (Hamidy et al. Herpetol. Rev. 41:66–67; Riehl et al. 2008. Herpetol. Rev. 39:77–78).

Rhacophorus v. viridis is a common species distributed in the Okinawa Islands, Ryukyu Archipelago, occurring in forests from lowlands to montane regions. On 9 May 2011 at 1955 h, I detected the spider *Heteropoda* cf. *simplex* (Sparassidae) grasping the abdominal region of a recently metamorphosed *R. v. viridis* at a garden pond of Nakagami-gun, Okinawa Prefecture, Japan (Fig. 1). The air temperature was 25.2°C and relative humidity was 88%. The spider with its prey was first found on the underside of an *Asplenium setoi* leaf, located ca. 1.5 m above water surface and 18 cm above the ground. The frog was immobile, probably due to paralysis caused by the spider venom. Unfortunately, the spider was disturbed by photography and escaped into vegetation.

Metamorphosing *R. v. viridis* descend to the terrestrial habitat with an unabsorbed long tail. When darkness approaches, metamorphosing frogs move away from the pond to climb surrounding vegetation. Mean snout–vent length of newly metamorphosed *R. v. viridis* is 20.6 ± 0.86 mm SD (range 18.0–22.5 mm, N = 74). It takes about two days to absorb the tail. As the prey frog in this case had a relatively long tail, it was likely captured by the spider shortly after leaving the water. The spider (cephalothorax + abdomen) was estimated at ca. 2 cm in length.

FIG. 1. The spider *Heteropoda* cf. *simplex* grasping a metamorphosed *Rhacophorus v. viridis*.

RHAEBO HAEMATITICUS **(Litter Toad) and** ***CRAUGASTOR FITZINGERI*** **(Fitzinger's Rain Frog). REPRODUCTIVE BEHAVIOR.** *Rhaebo haematiticus* and *Craugastor fitzingeri* are common tropical leaf litter frogs that can be found sympatrically from Honduras to Colombia in lowland and premontane wet and moist forests. *Rhaebo haematiticus* is a moderate-sized toad (males 42–62 mm SVL, females 50–80 mm) that reproduces

FIG. 1. Male *Craugastor fitzingeri*, a terrestrial breeder, in amplexus with female *Rhaebo haematiticus*, an aquatic breeder, in the leaf litter at La Selva Biological Station, Costa Rica.

by depositing strings of eggs in rocky pools along streams. *Craugastor fitzingeri* is also moderately sized but is generally smaller (males 24–35 mm SVL, females to 52 mm) and likely reproduces by depositing terrestrial, direct-developing eggs (Guyer and Donnelly 2004. Amphibians and Reptiles of La Selva, Costa Rica and the Caribbean Slope: A Comprehensive Guide. Univ. California Press, Berkeley).

Interspecific amplexus has been reported numerous times for anurans, both among closely related species that in some cases can create hybrid offspring (Lamb et al. 1990. J. Evol. Biol. 3:295–309; Christman et al. 2000. Herpetol. Rev. 31:99–100; Lind et al. 2003. Herpetol. Rev. 34:234–235; Ritchie et al. 2008. Herpetol. Rev. 39:80; Turner 2012. Herpetol. Rev. 43:123) and among more distantly related and dissimilar species (Grogan and Grogan 2011. Herpetol. Rev. 42:89–90; Manzano and Corzas 2011. Herpetol. Rev. 42:84; Streicher et al. 2010. Herpetol. Rev 41:208). Misdirected amplexus has also been reported with inanimate objects (Streicher 2008. Herpetol. Rev. 39:75). Instances of breeding interference due to interspecific amplexus may negatively affect species demographics of sympatric species (Pearl et al. 2005. Am. Midl. Nat. 154:126–134). Here, we report amplexus between two individuals of markedly different sizes from unrelated taxa with different reproductive modes.

At 1442 h on 22 Aug 2012, a male *C. fitzingeri* was observed in amplexus with a large female *R. haematiticus* in the Arboretum at the La Selva Biological Station in Sarapiquí, Costa Rica (10.430055°N, 84.011102°W). They were sighted when the observers were 50 cm in approach distance from the pair, and the female *R. haematiticus* jumped. Jumping did not appear to interfere with amplexus. The frogs maintained their position until at least 1510 h when the observers returned to take more photos. The frogs were found in an area that is maintained with regular mowing, under the shade and leaf litter of mature *Casearia corymbosa* and *Hieronyma alchorneoides* trees.

***RHINELLA MARINA* (Cane Toad). DIET.** The diet of *Rhinella marina* has been reported by several authors (Zug and Zug 1979. Smithson. Contrib. Zool. 284; Murray and Lampo 1996. J. Herpetol. 30[1]:73–76). Its diet is mostly composed of insects and

FIG. 1. *Rhinella marina* preying on a juvenile Southwestern Cat-eyed Snake (*Leptodeira maculata*), at Playa Linda Ixtapa–Zihuatanejo, Guerrero, Mexico.

different species of invertebrates. There are also reports on the predation of *R. marina* on several species of vertebrates (Lever 2001. The Cane Toad. Westbury, Otley; Beckmann and Pizzato 2011. Herpetol. Rev. 42[4]:592). Snakes (*Typhlops*) have been reported as food in a study of its natural distribution in the Philippine Islands (Rabor 1952. Copeia 1952:281–282).

On 10 April 2011 on the Pacific Coast in Playa Linda Ixtapa–Zihuatanejo (17.681986°N, 101.644333°W), Guerrero, Mexico, we found a *R. marina* preying on the semiaquatic colubrid snake, *Leptodeira maculata*. Both animals were observed at 2130 h in a tropical deciduous forest, at about sea level. The toad and snake were photographed and left without disturbance. This is the first report of predation on a snake by *R. marina* in its natural distribution.

Mexico (e-mail: gcasas@ibiologia.unam.mx).

***RHINELLA SCHNEIDERI* (Cururu Toad). PREDATION.** Anurans are often a food source of passerines and other bird species in neotropical forests (Poulin et al. 2001. J. Trop. Ecol. 17:21–40). Some species of birds are dietary generalists and opportunistically prey on anurans (Toledo et al. 2007. J. Zool. 271:170–177).

Rhinella schneideri is a large toad included in the *Rhinella marina* group (Pramuk et al. 2007. Global Ecol. Biogeogr. 16:1–12), and is widely distributed in South America (Pramuk 2006. Zool. J. Linn. Soc. 146:407–452). This species is commonly found in open, urban areas and has a wide distribution in South America, from the Atlantic coast (Ceará to Rio Grande do Sul, Brazil), eastern Amazon in Paraguay, Bolivia, Argentina, and Uruguay (Frost 2011. Amphibian Species of the World: an Online Reference. Ver. 5.5. http://research.amnh.org/vz/herpetology/amphibia/; American Museum of Natural History, New York), occurring also in Brazilian savannah (Colli et al. 2002. *In* Oliveira and Marquis [eds.], The Cerrados of Brazil: Ecology and Natural History of a Neotropical Savanna, pp. 223–241. Columbia Univ. Press, New York).

The Guira Cuckoo, *Guira guira*, is a species of the subfamily Crotophaginae and is widely distributed through South America

(Sick 1997. Ornitologia Brasileira. Editora Nova Fronteira, Rio de Janeiro. 912 pp.). This species is common in areas affected by human activities, including deforested areas, urban areas, and crop fields (Mesquita 2009. Ararajuba 17:84–85). Here we report the attempted predation of a juvenile *R. schneideri* by the Guira Cuckoo.

On 7 Jan 2012 around 0915 h, in a semi-deciduous forest fragment near a swampy area in the Baguaçú Ecological Park (21.22000°S, 50.42833°W; 353 m elev.), in an urban area of Araçatuba, state of São Paulo, Brazil, we heard the vocalization of a group of Guira Cuckoos on the aquatic macrophyte, *Pistia stratiotes*, in a swampy area. After a few minutes, the birds were photographed during flight, with one of the individuals holding a juvenile *R. schneideri*. The bird grasped the toad by its hind leg, thereby avoiding the parotoid macroglands (Fig. 1). The *R. schneideri* was identified by the presence of the parotoid macroglands from digital photographs taken with a Canon EOS 7D with a Canon 100–400 mm f/4.5-5.6L lens.

Species of the genus *Rhinella* produce toxic secretions from the skin and parotoid macroglands, protecting them from predators (Cardoso and Sazima 1977. Cienc. Cult. 29:1130–1132). However, our observations do not allow us to say if the poison is effective against the Guira Cuckoo.

Our record suggests that anurans that produce toxic secretions for defense are subject to opportunistic predation by generalist species of birds such as the Guira Cuckoo. Predation of other anurans by the Guira Cuckoo is rare and limited to few reports: *Physalaemus* cf. *fuscomaculatus* (Kokubum and Zacca 2003. Herpetol. Rev. 34:232–233), *Leptodactylus ocellatus* (Repenning et al. 2009. Zoologia 26:443–453), *Rhinella granulosa* (Mesquita 2009, *op. cit.*), *Rhinella* cf. *henselli* (Gomes 2009. Atual. Ornitol. 151:8–9), and *Pseudis platensis* (Landgref-Filho et al. 2011. Herpetol. Rev. 42[1]:90). We believe that our record probably represents an attempted predation, rather than predation *per se*, because the toad was alive when observed.

We thank D. L. Santos for suggestions on earlier versions of this manuscript, P. S. Bernarde for identification of the *R. schneideri*, and T. S. Ribeiro for corrections and suggestions on the English translation. The Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES) provided financial support to F. H. Oda.

***SCAPHIOPUS HURTERII* (Hurter's Spadefoot). LEUCISM.** Leucism (or partial albinism) is a condition in which an animal lacks most or all of the melanin in its skin but retains most of the pigment in its eyes (in true albinism the eye pigment is lacking as well; Warham 2005. Elsevier's Dictionary of Herpetological and Related Terminology. Bournemouth, England. 227 pp.). Both leucism and albinism have been reported in a number of anurans including the American Bullfrog (*Lithobates catesbeianus*; Mitchell and McGranaghan 2005. Banisteria 25:51), Foothill Yellow-legged Frog (*Rana boylii*; Norman and Moller 2002. Bull. Chicago Herpetol. Soc. 37:2–3), and Burrowing Toad (*Rhinella fernandezae*; Lopez and Ghirardi 2011. Belg. J. Zool. 141:59–61). In this note, we report the first documented occurrence of leucism in *Scaphiopus hurterii*.

On 5 May 2012 at Boehler Seeps and Sandhills Preserve, located in Atoka Co., Oklahoma, USA (34.17091°N, 95.88964°W) we encountered a recently metamorphosed (SVL 16 mm), leucistic *S. hurterii*. Its skin was a light pink color except for its dermal tubercles, which were red with a black spot in the middle (Fig. 1). Its eyes were largely black, but they retained some of their normal gold coloration. The eyes appeared blue when viewed through the skin. Its ventral surface was transparent, and internal organs could be seen through the skin.

During the summer of 2012, 433 recently metamorphosed *S. hurterii* were captured in traps, and many others were randomly encountered, but this was the only one that was leucistic. Both leucism and albinism have been reported in tadpoles of the Eastern Spadefoot (*S. holbrookii*), but to our knowledge this is the first report of leucism in *S. hurterii* (Feinberg and Hoffmann 2004. Herptol. Rev. 35:377; Johnston and Johnston 2006. Herptol. Rev. 37:211–212).

FIG. 1. Leucistic *Scaphiopus hurterii* alongside a normally pigmented conspecific.

DONALD T. McKNIGHT (e-mail: Donald222@live.missouristate.edu) and **DAY. B. LIGON**, Department of Biology, Missouri State University, 901 South National Avenue, Springfield, Missouri 65897, USA.

ZACHAENUS CARVALHOI **(Carvalho's Bug-eyed Frog). REPRODUCTION.** *Zachaenus carvalhoi* is a little-known species that occurs in the leaf litter of the Atlantic Rainforest in few localities of southeastern Brazil (Sales and Maciel 2010. Check List 6:458–459). *Zachaenus carvalhoi* and *Z. parvulus* are the only members of the genus. *Zachaenus carvalhoi* is categorized as Data Deficient in the IUCN Redlist, due to the lack of information on its occurrence and biology. On 18 Oct 2010, an adult female *Z. carvalhoi* (34.8 mm SVL) was captured in a pitfall trap inside a forested area in the Serra Brigadeiro State Park (20.7219°S, 42.4786°W, SAD 1969; 1380 m elev.), in the municipality of Araponga, Minas Gerais state, Brazil. The specimen was sacrificed using 5% xylocain cream, and preserved in 10% formalin. After dissection, 37 eggs were found; average egg diameter was 3.5 ± 0.16 mm (3.14–3.78 mm). The voucher was deposited in the herpetological collection of the Museu de Zoologia João Moojen, Universidade Federal de Viçosa, Minas Gerais, Brazil (MZUFV 10642).

Both body size (34.8 mm SVL) and clutch size (37 eggs) reported herein are greater than those for *Z. parvulus*, where the mean body size was 21.1 ± 5.7 mm (12.7–10.9; N = 29) and clutch size was 12.6 ± 2.6 eggs (10–16; N = 9) (Van Sluys et al. 2001. J. Herpetol. 35:322–325). However, the eggs size of *Z carvalhoi* (mean diameter 3.47 mm) is within the range (1.5–4.2 mm) reported for *Z. parvulus* (Van Sluys et al. 2001, *op. cit.*). There was no relationship between female body size (FBS) and number of eggs reported for *Z. parvulus*, although the authors suggested the small sample size influenced the analysis. Additional studies are necessary to clarify the relation between FBS and clutch size in *Z. carvalhoi*.

We thank Universidade Federal de Viçosa for logistic support and Fundação de Amparo à Pesquisa do Estado de Minas Gerais (FAPEMIG, CRA-APQ-02370-09) for financial support. The collecting permits were provided by the Instituto Brasileiro do Meio Ambiente e dos Recursos Naturais Renováveis (IBAMA) #20857-2 and Instituto Estadual de Florestas (IEF) #071-09ii.

TESTUDINES — TURTLES

CHELYDRA SERPENTINA **(Snapping Turtle). NEST INUNDATION.** As part of a study of Wood Turtle (*Glyptemys insculpta*) nesting ecology in Nova Scotia, Canada, nests were recorded and covered with predator exclusion screens. During this study a *Chelydra serpentina* was observed nesting in the area on 21 June 2008; although the nest was not covered, its location was noted. On 2 August 2008, heavy rains caused the water to rise in the river and flood the nest beach containing this *C. serpentina* nest as well as six Wood Turtle nests. The beach remained inundated for five days.

When the water receded one egg from each of three Wood Turtle nests was excavated, removed, and dissected; all three embryos were dead. Subsequently, all Wood Turtle eggs and the eggs from the known *C. serpentina* nest were excavated and removed for dissection. All 22 fertile Wood Turtle eggs contained dead embryos, ranging from 40–58 days of development. However, of the first three *C. serpentina* eggs dissected, two contained live embryos. The remaining 12 eggs were allowed to complete incubation. Eight eggs hatched following a total incubation time of 78–81 days. Of the remaining four eggs, three had no visible development and one contained a fully developed embryo that failed to emerge.

Of the eight *C. serpentina* hatchlings, three had some form of visible deformity. Two had a minor deformity in the form of a slightly crooked, or bent, tail. The third was more severe, with the tail curving 360 degrees, a misshapen carapace, and an apparent inability of the hatchling to open its mouth to feed. In comparison, of 38 *C. serpentina* hatchlings from two clutches that were not inundated, no deformities were observed.

As the excavated *C. serpentina* eggs were originally assumed to be dead, they were not handled gently and spent some time in a moving vehicle without appropriate substrate. Consequently, it is unknown if the deformities of these hatchlings resulted from egg handling or temperature extremes during early development, the inundation, or genetic anomalies.

WENDY HOLMAN (e-mail: wendygholman@gmail.com), **STEVE MOCKFORD** (e-mail: stephen.mockford@acadiau.ca), and **TOM HERMAN**, Biology Department, Acadia University, Wolfville, Nova Scotia, B4P 2R6, Canada.

CHRYSEMYS PICTA **(Painted Turtle). SIAMESE TWINS.** At ca. 0900 h on 13 April 2002, while searching a residential area around a pond in Wayne Co., Indiana, USA (39.7975°N, 84.96388°W) for spring-emerging hatchling Painted Turtles, I noticed an open Painted Turtle nest cavity (not uncommon in April in this area). Upon closer inspection, it was clear that the cavity had been breached by emerging hatchlings, but that two hatchlings remained in the nest because they were not capable of crawling out. Although fully developed, of near equal size, and very active (Fig. 1), they had been unable to leave the nest cavity because they were conjoined along the plastral midline. Twinning in turtles is not uncommon (e.g., Tucker and Janzen 1997. Copeia 1997:166–173; and references therein); however, this is the first record for the widespread and common Painted Turtle. In

FIG. 1. Conjoined twins of *Chrysemys picta* found in nest cavity in Indiana.

addition, my observation demonstrates that conjoined twins are capable of overwintering successfully in the nest, but also suggests that in nature they probably are unable to leave the nest due to locomotor difficulties.

JOHN B. IVERSON, Department of Biology, Earlham College, Richmond, Indiana 47374, USA; e-mail: johni@earlham.edu.

***LEPIDOCHELYS OLIVACEA* (Olive Ridley Seaturtle). ASSOCIATION WITH *PLANES MARINUS* (Columbus Crab).** *Lepidochelys olivacea* has a wide-ranging distribution in tropical and subtropical oceans, and is perhaps the most abundant species of the Cheloniidae (Plotkin 2007. Biology and Conservation of Ridley Sea Turtles. John Hopkins University Press, Baltimore, Maryland. 356 pp.). *Planes* is a genus of small oceanic crabs also widespread in the tropical and subtropical areas of the world, all known as Columbus crabs. Three species are currently recognized; *Planes marinus* is recorded in Brazil from the states of São Paulo throughout Santa Catarina (Melo 1996. Manual de Identificação dos Brachyura [Caranguejos e Siris] do Litoral Brasileiro. Plêiade/Fapesp, São Paulo. 603 pp.). An association between Columbus crabs and cheloniid turtles is well-known, however the nature of this relationship has been controversial. An older view suggested that the crabs feed on turtles feces, but recent authors suggest a mutualistic relationship, where the crabs feed on turtles' parasites during the day and use the turtles as floating devices to feed on neuston at night (Davenport 1994. J. Mar. Biol. Assoc. U.K. 74:735–737; Frick et al. 2004. J. Crustacean Biol. 24[2]:350–355). According to Frick et al. (*op. cit.*), the crabs benefit the turtles by eating the encrusting parasites, thus improving their hydrodynamics, while the carapaces of the turtles provide shelter, food, and dispersion capability for the crabs. Despite these possible advantages, *P. marinus* was the only species of the genus that had never been reported as an sea turtle epibiont (Frick et al. 2006. Mar. Turt. Newsl. 111[4]:12–14). The first report of this association was from the Hawaiian Islands to the eastern tropical Pacific Ocean (Frick et al. 2011. Mar. Biol. 158:1699–1708). Here, we present the first known occurrence of *P. marinus* in association with sea turtles in the Atlantic Ocean. Also, the known area of occurrence of the crab is expanded to the northeastern coast of Brazil. We found three specimens of *P. marinus* on two *Lepidochelys olivacea* collected in the Economic Exclusive Zone of Northeastern Brazil (ZEE-NE). The turtles were collected accidently by the longline fishery vessel Ghandi. The turtles were inspected, photographed, and released. The crabs were collected between the tail and the carapace of the turtles (Fig. 1), fixed in 70% ethanol, and deposited in the carcinological collection of the Museum of Zoology of the University of São Paulo (MZUSP 27695). The two ovigerous females and one adult male were collected between 24 and 29 August 2004. The geographic coordinates are 1.55°S, 30.13°W and 1.23°S, 30.33°W for the females and male, respectively.

FIG. 1. Ecological association between *Lepidochelys olivacea* and the crab *Planes marinus*.

SANTANA**, Universidade Sagrado Coração – USC, Rua Irmã Arminda, 10-50, Jd. Brasil, 17011-160 Bauru, SP, Brazil.

***STERNOTHERUS MINOR* (Loggerhead Musk Turtle). DIET.** *Sternotherus minor* is primarily a riverine species and is known as an opportunistic dietary generalist. Its diet consists of a variety of aquatic food items, especially insects and mollusks. As body size increases, head morphology characteristics, including hypertrophied head muscles and broadened alveolar plates, also change allowing for feeding heavily on mollusks (Ernst and Lovich 2009. Turtles of the United States and Canada. Johns Hopkins University Press, Baltimore, Maryland. 827 pp.). Most reports on the diet of *S. minor* are from Florida spring habitats (Berry 1975. Copeia 1975:692–701). Here, we report on a snake-skin shed from a diet sample of *S. minor*.

At 1230 h on 4 August 2012, we captured an individual female *S. minor* (maximum straight-line carapace length = 112.26 mm) in a fish-baited hoop trap near the confluence of Ichawaynochaway and Chickasawhatchee Creeks in Baker Co., Georgia, USA. Following the capture, the individual was cleaned by scrubbing the carapace and plastron to remove any mud and algae. The axillary and inguinal regions of the turtle were scrubbed and rinsed and leeches were removed from all parts of the body. The individual was kept in a plastic bin with two liters of stream water. The bin was covered by window screening secured by binder clips to not allow the turtle to escape. At the end of six hours, fecal material was found in the bottom of the tank and several pieces of snake shed were discovered, including both ventral and dorsal snake scales. The snake shed had long, highly keeled scales. As far as we know, snake-skin shed, of any species, has not been reported in the diet of *S. minor*. Although identification of the snake shed to species level was not possible, we suspect the shed belonged to the genus *Nerodia*. The Brown Watersnake (*Nerodia taxispilota*) is a common species found along the margins of streams in Georgia, and was observed multiple times while trapping this reach of Ichawaynochaway Creek.

Shed snake skin has also been found in the diet of Eastern Mud Turtle (*Kinosternon subrubrum*) from riverine habitat (Steen et al. 2012. Herpetol. Rev. 43:639). Dermatophagy (shed-skin eating) has been described for several groups of amphibians and reptiles, but often occurs by individuals eating their own skin or that of conspecifics (Weldon et al. 1993. J. Herpetol. 27:219–228). *Sternotherus minor* has been reported to eat carrion and non-nutritional foods like rock and detritus that are assumed to have been accidentally swallowed (Folkerts 1968. J. Herpetol. 2:171–173). They are also known to feed among algal mats and other substrates and it is possible that this is how the snake shed was ingested.

We thank John Jensen, Kevin Stohlgren, Andrew Durso, and David Steen for help in attempting to identify the snake species.

SEAN C. STERRETT (e-mail: ssterret@uga.edu) and **VANESSA C. K. TERRELL** (e-mail: vkinney@uga.edu), Warnell School of Forestry and Natural Resources, University of Georgia, 180 E. Green Street, Athens, Georgia 30605, USA.

***TERRAPENE CAROLINA TRIUNGUIS* (Three-toed Box Turtle). DIET.** *Terrapene carolina* is considered omnivorous, eating a wide variety of plant and animal foods. Mammals documented as food items, typically as carrion, include mice (*Mus musculus*, *Peromyscus leucopus*, *P. maniculatus*), voles (*Microtus pennsylvanicus*), shrews (*Blarina* sp., *Cryptotis parva*, *Sorex* sp.), and a bovine (*Bos taurus*) (Ernst and Lovich 2009. Turtles of the United States and Canada. 2nd ed. Johns Hopkins University Press, Baltimore, Maryland. 827 pp). On 19 August 2012, on the Camp Shelby Joint Forces Training Center, Forrest Co., Mississippi, USA, a female *Sigmodon hispidus* (Hispid Cotton Rat) was found dead (of unknown causes) in a box trap and was discarded ~5 m away from the trap. The next day we observed an adult male *T. c. triunguis* eating the carcass and entrails of the *S. hispidus*. As we approached, the turtle took a bite of the entrails and then started to slowly walk away from us, at which time the turtle was captured and processed (i.e., sexed, measured, and marked).

JAMES R. LEE (e-mail: jlee@tnc.org) and **DUSTIN SHANEYFELT**, The Nature Conservancy, Camp Shelby Joint Forces Training Center, CSJFTC-ENV Bldg. 6530, Camp Shelby, Mississippi 39407, USA.

***TERRAPENE CAROLINA TRIUNGUIS* (Three-toed Box Turtle). DIET.** *Terrapene carolina triunguis* is the western-most subspecies of *T. carolina* and has a range that stretches from southeast Kansas and central Missouri south to the Gulf Coast (Conant and Collins 1998. A Field Guide to Reptiles and Amphibians of Eastern and Central North America. 3rd ed. Houghton Mifflin Co., Boston, Massachusetts. 616 pp.). Three-toed Box Turtles are omnivorous and consume a wide variety of food items (Ernst et al. 1994. Turtles of the United States and Canada. Smithsonian Institution, Washington D.C. 578 pp.). It has been suggested that *Terrapene carolina triunguis* may be a seed disperser for some plants (Braun and Brooks 1987. Amer. Midl. Nat. 117:31–318).

On 6 April 2012, we observed a *T. carolina triunguis* eating a berry of an exotic invasive *Nandina domestica* (Berberidaceae; Nandina, Sacred Bamboo) plant (Fig. 1) in the yard of a residence in Nacogdoches Co., Texas, USA (94.668382°N, 31.592993°W; WGS84). Nandina naturally ranges from central China to India and has been cultivated in Japan for many centuries (Chongxi and Foster 1985. Herbal emissaries. Healing Arts Press, Rochester, Vermont. 356 pp.). Nandina was introduced into the United States in 1804 for use as an ornamental plant (Wyman 1969. Shrubs and Vines for American gardens. Revised ed., Collier-Macmillian, Toronto, Ontario. 613 pp.). It is naturalized in North Carolina (Radford et al. 1964. Guide to the Vascular Flora of the Carolinas. University of North Carolina Press, Chapel Hill. 383 pp.) and is suspected to have invaded nine states throughout the southeastern United States, including Texas (Miller 2003. Nonnative Invasive Plants of Southern Forests: a Field Guide for Identification and Control. USDA Forest Service Gen. Tech. Rep. SRS–62. USDA Forest Service Southern Research Station, Asheville, North Carolina). It has been suggested that Nandina is dispersed by birds and mammals (Ludlow 1995. Florida Department of Environmental Protection, Resource Management Notes 6:4–5). In this note we document a previously unknown food item for *T. carolina triunguis* as well as an additional possible species for seed dispersal of invasive *Nandina domestica*.

FIG. 1. *Terrapene carolina triunguis* eating a berry of an exotic invasive *Nandina domestica* plant.

CORY K. ADAMS (e-mail: coryadams@fs.fed.us), Southern Research Station, USDA Forest Service, Nacogdoches, Texas 75965, USA; **JENNIFER H. ADAMS**, 1009 Lock St., Nacogdoches, Texas 75964, USA.

***TERRAPENE ORNATA LUTEOLA* (Desert Box Turtle). NESTING/ HATCHLING OVERWINTERING/ HATCHLING DIET.** Hatchling *Terrapene ornata ornata* are known to either emerge from the nest cavity during the fall of the year they hatched, or to spend the winter beneath the nest cavity after hatching (Doroff and Keith 1990. Copeia 1990:387–399; Costanzo et al. 1995. Ecology 76:1772–1785; Converse et al. 2002. Am. Midl. Nat. 148:416–422). However, no published information exists on the emergence behavior of hatchling *T. o. luteola*, the westernmost subspecies of *T. ornata*. The following observations were made ca. 2 km E of US Hwy 54, ca. 20 km S of Alamogordo, New Mexico, USA (32.69611°N, 105.98053°W, WGS84; 1225 m elev.).

On the evening of 14 July 2002, a gravid female *T. o. luteola* was observed in the early stages of digging a nest. Earlier in the day, the region had received its first monsoonal rain of the year, and puddles of water were evident. Approximately 2 h before sunset this turtle was observed in the open, digging with its forelimbs into a small depression. My presence disturbed the animal, which retreated to a nearby mesquite bush. The animal was left, but checked on again immediately before dark. It had returned to the same depression, and was in the process of burying itself, which typically precedes construction of the actual nest cavity.

The site was re-visited on the morning of 15 July, and an empty hole was observed. The recent rainfall had only moistened the soil to a depth of several cm, beyond this depth a clear demarcation was visible between the wet surface, and the powder-dry subsurface, and it was assumed that moisture was insufficient to complete the nest. The site was re-visited on 19 July, after more rain had fallen. At 1045 h during overcast and humid conditions, I observed the same female about 50 m from her original nesting attempt on a slightly raised patch of bare ground next to a small depression with a scraped over appearance. It was clear that she had just finished covering a nest. The nest was excavated to ascertain the presence of eggs. At least one egg was noted at a depth of 25 cm, and the nest was immediately reburied. The nest was securely protected with a cage made of hardware cloth and rebar, and camouflaged with woody debris. On 4 October,

PHOTO BY IAN MURRAY

FIG. 1. Hatchling *Terrapene ornata luteola* feeding on Thread-leaf Groundsel (*Senecio flaccidus* var. *douglasii*) petals on 6 October 2008.

FIG. 1. Aftermath of predation attempt by *Paleosuchus trigonatus* on the porcupine *Coendou bicolor*.

the nest was again excavated, revealing two hatchlings buried in the bottom of the nest cavity. The nest was carefully re-buried and covered. On 27 June 2003, the area received its first summer rainfall, and the nest was visited, but no emergence noted. On 29 June the site was visited once again, and 2 hatchlings (SCL = 38.1, 36.3 mm) were noted on the surface, under the cage (MSB 78220, 78221). The cavity was exhumed, revealing that out of a clutch of three eggs, two had been viable. These young remained within the nest cavity for at least 266 days. To my knowledge, this is the first documented case of hatchling *T. o. luteola* overwintering in the nest. Additionally, hatchling emergence may vary based on geography or local rainfall patterns.

Observations on captive 'backyard' turtles in Albuquerque, New Mexico (35.08482°N, 106.61151°W, WGS84; 1578 m elev.) also indicate that hatchlings overwinter within the nest cavity and emerge the following summer. However, on 6 October 2008, I observed a hatchling *T. o. luteola* (SCL = 38.4 mm, 12.9 g) active on the surface and feeding on Thread-leaf Groundsel petals (*Senecio flaccidus var. douglasii*) in a central New Mexico population on the Sevilleta National Wildlife Refuge (34.401643°N, 106.662123°W, WGS84; 1567 m elev.). Not only do these observations suggest plasticity for hatchling *T. o. luteola* emergence, but this feeding record adds to the paucity of information available describing hatchling *T. ornata* feeding ecology (Fig. 1).

I thank Jon Erz and the Sevilleta National Wildlife Refuge for research access (special use permit 22522 08-018).

IAN W. MURRAY, School of Physiology, Faculty of Health Sciences, University of the Witwatersrand, Parktown, 2193, Johannesburg, South Africa; e-mail: imurray@unm.edu.

CROCODYLIA – CROCODILIANS

***PALEOSUCHUS TRIGONATUS* (Schneider's Smooth-fronted Caiman). PREY.** Despite being a widespread species, the natural history of the Schneider's Smooth-fronted Caiman (*Paleosuchus trigonatus*) is little known due to its habitat preferences and cryptic behavior (Magnusson and Lima 1991. J. Herpetol. 25:41–48). Its main habitat comprises the closed-canopy streams and rivers of forested regions through the Amazon and Orinoco drainage basins and the fluvial coastal systems of the Guyanas (Magnusson and Campos 2010. *Paleosuchus trigonatus*. Crocs. CSG:43–45). Like all crocodilians, *P. trigonatus* is a generalist predator consuming a wide variety of prey, however, its diet includes a higher proportion of terrestrial vertebrates than other Amazonian alligatorids (Magnusson et al. 1987. J. Herpetol. 21:85–95).

On 5 February 2011 at 1030 h, we witnessed a unusual predation attempt by a *Paleosuchus trigonatus* (ca. 150 cm total length) on a porcupine (*Coendou bicolor*) at Playas de Cuyabeno (0.31428°S, 75.96146°W, 213 m elev.), Reserva de Producción Faunística Cuyabeno, Sucumbíos Province, Ecuador. The locality lies within tropical rainforest and the observation was made during the dry season, which extends from December to March in this region. We could not determine if the predation attempt was successful, but it was evident that the caiman attacked the porcupine, as its head and jaws were covered with quills (Fig. 1). When captured, the caiman appeared stressed, as the porcupine's quills (up to 5 cm long) had penetrated 0.5 cm into the flesh of caiman. The caiman was covered by leaf litter under a large, overhanging horizontal root, at a small salt lick with footprints of several mammals evident, suggesting that the caiman attacked the porcupine nearby. Magnusson et al. (1987, *op. cit.*) reported that adult *P. trigonatus* consumed mammals such as rats (*Oryzomys* sp. and *Proechimys* sp.), agouti (*Dasyprocta* sp.), monkey (undetermined), a marsupial (*Metachirus nudicaudatus*), armadillo (*Dasypus novemcinctus*), and porcupine (*Coendou* sp.) in Central Amazonia, Brazil. Therefore, our observation supports predation on porcupines, and suggests that adult *P. trigonatus* forage near salt licks.

We thank Francisco Villamarín for comments on this note.

DIEGO A. ORTIZ (e-mail: ortizdiego5@gmail.com), Museo de Zoología, Escuela de Biología, Pontificia Universidad Católica del Ecuador, Av. 12 de Octubre 1076 y Roca, Aptdo. 17-01-2184, Quito, Ecuador, **RAQUEL BETANCOURT** (e-mail: raquem_by@hotmail.com) and **MARIO H. YÁNEZ-MUÑOZ** (e-mail: mayamu@hotmail.com), División de Herpetología, Museo Ecuatoriano de Ciencias Naturales, Rumipamba 341 y Av. de los Shyris, Quito, Ecuador.

LIZARDS — SQUAMATA

***ACANTHODACTYLUS BOSKIANUS* (Bosk's Fringe-fingered Lizard). BIFURCATION.** *Acanthodactylus boskianus* is a diurnal, ground dwelling, medium to large-sized lacertid lizard. It is one of the most widespread species of the genus ranging from West Sahara, through all of North Africa (including the Sahel) to the Arabian Peninsula and east to SW Iran northwards to Southern Turkey (Sindaco and Jeremcenko 2008. The Reptiles of the Western

FIG. 1. Adult *Acanthodactylus boskianus asper* with bifurcated tail.

Palearctic. Edizioni Belvedere, Latina, Italy. 579 pp.). *Acanthodactylus boskianus* usually occurs in arid and desert ecosystems and is an ecologically plastic species which occurs on variety of habitats, typically inhabits coarse substrates with moderate vegetation. This species is often the most conspicuous and abundant lizard in arid and desert regions in its distribution range.

On 12 May 2011 we captured three adult individuals of the subspecies *A. b. asper* in an open area with thorny bushes in Wadi Paran, southern Israel (30.337°N, 34.946°E). Lacertids are known to readily autotomize their tails (Fitch 2003. J. Herpetol. 37:395–399; Pafilis et al. 2009. Evolution 63:1262–1278). In order to collect tissue samples from these specimens we cut the tips of their tails, and kept the animals alive for breeding at the I. Meier Segals Garden for Zoological Research at Tel-Aviv University (collection was done under INPA permit # 38074). The specimens were kept in plastic terraria, and their tails regenerated. In one female (Fig. 1; 66 mm SVL; 6.6 g), the regenerated tail had bifurcated 4 cm posterior from the cloaca, with both tail tips at even lengths of 50 mm. This individual is the only *Acanthodactylus* specimen (out of 46 individuals we kept, belonging to six species) that did not flee in the presence of humans. We did not observe bifurcated tails in *Acanthodactylus* specimens in the field, nor did we among the >1000 specimens (in 9 species, including 391 *A. boskianus* specimens) kept at the Tel-Aviv University Zoological Museum.

KARIN TAMAR (e-mail: karintmr@post.tau.ac.il), **EREZ MAZA** (e-mail: mazaerez@post.tau.ac.il) and **SHAI MEIRI** (e-mail: uncshai@post.tau.ac.il), Department of Zoology, Tel-Aviv University, Tel-Aviv 69978, Israel.

***AMPHISBAENA ALBA* (Giant Worm Lizard). PREDATION.** *Amphisbaena alba* is a species widely distributed in South America (Gans 2005. Bull. Am. Mus. Nat. Hist. 289:1–130). In Brazil is found in different ecosystems, where it is primarily fossorial (Moura et al. 2011. *In* Herpetologia do Estado de Pernambuco. 440 pp.; Vitt et al. 2008. *In* Guia de Lagartos da Reserva Adolpho Ducke - Amazônia Central. 175 pp.). This species can be an important prey item for some bird species, being reported in the diet of the hawk *Rupornis magnirostris* in an area of Atlantic Forest in southern region of Brazil (Santos and Rosado 2009. Revista em Agronegócios e Meio Ambiente 2:421–430). The White-naped Jay (*Cyanocorax cyanopogon*) is a bird endemic to Brazil, belonging to the family Corvidae. It is a generalist and has the habit of forming conspecific aggregations (Sick 1997. Ornitologia Brasileira. Editora Nova Fronteira, Rio de Janeiro, Brazil. 912 pp.).

PHOTO BY LEONARDO BARBOSA DA SILVA

FIG. 1. Predation of *Amphisbaena alba* by *Cyanocorax cyanopogon* in the Floresta Nacional do Araripe, Ceará, Brazil. Record: CHP-UFRPE N°2800.

On 20 August 2012 at 0740 h, at the edge of a forested area located in Floresta Nacional do Araripe (7.3838°S, 39.3544°W; WGS 84), Ceará, Brazil, we observed a group of five individuals of *C. cyanopogon* preying on an individual of *A. alba* (Fig. 1). The prey was on the ground when five jays approached, emitting intense vocalizations. Two individuals of the group attacked the amphisbaenian, pecking it in the head and tail with their beaks. A third individual then joined them and also began to peck the prey. When the *A. alba* ceased resistance, it was taken into the forest, where other individuals of the group approached and began to feed on the prey. This is the first record of predation reported for *A. alba* by *C. cyanopogon* in the northeastern region of Brazil. The images of predation were filed in the Collection of Herpetological and Paleoherpetological of Federal Rural University of Pernambuco - UFRPE, Recife, Pernambuco, Brazil.

We acknowledge the direction of Floresta Nacional do Araripe for permission to carry out the research.

LEONARDO BARBOSA DA SILVA (e-mail: lb_silva@yahoo.com.br), **JACILENE BEZERRA DA SILVA** and **GERALDO JORGE BARBOSA DE MOURA** (e-mail: geraldojbm@yahoo.com.br), Lab. de Estudos Herpetológicos e Paleoherpetológicos da Universidade Federal Rural de Pernambuco, UFRPE, Programa de Pós-graduação em Ecologia, Rua Dom Manoel de Medeiros, s/n, Dois Irmãos, CEP: 52171-900, Recife, Pernambuco, Brazil.

***ANOLIS CAROLINENSIS* (Green Anole). PREDATION.** A wide variety of predators have been documented for Green Anoles, including birds (e.g., Arndt 1975. Florida Sci. 58:249–251; Palmer and Braswell 1995. Reptiles of North Carolina. Univ. of North Carolina Press, Chapel Hill. 412 pp.), frogs (Hoffman and Johnson 2008. Herpetol. Rev. 39:339), snakes (Wharton 1969. Bull. Florida St. Mus. 14:227–272), other lizards, including conspecifics (Campbell and Gerber 1996. Herpetol. Rev. 27:106; Gerber and Echternacht 2000. Oecologia 124:599–607; Netting 1940. Copeia 1940:266), and wolf spiders (Corey 1988. J. Aranachol. 16:392–393). Orb web spiders usually catch and consume invertebrates, and are known to occasionally eat small vertebrates such as small snakes (Burt 1949. Herpetologica 5:127; Groves 1978. Bull. Maryland Herpetol. Soc. 14:44–46) and the lizards *Anolis porcatus* and *A. sagrei* in the Caribbean (Armas 2001. Revista Ibérica de Aracnologia 3:87–88; Armas and Alayón 1987. Poeyana 344:1–18). Here we describe the first successful predation of an *A. carolinensis* by an orb weaving spider.

FIG. 1. An *Anolis carolinensis* captured by the orb weaver *Neoscona domiciliorum*.

On 11 October 2008 on Jekyll Island, Glynn Co., Georgia (31.058333°N, 81.419444°W; WGS84), an adult *A. carolinensis* was observed wrapped in the web of a female orb weaver (*Neoscona domiciliorum*) (Fig. 1). Females of this spider are common in moist woodland habitats dominated by the live oak *Quercus virginiana* (Edwards 2003. Florida Coop. Ext. Service, DPI Entomology Circular 266, Gainesville, Florida. 4 pp.) where *A. carolinensis* may also be abundant (Jensen et al. 2008. Amphibians and Reptiles of Georgia. Univ. Georgia Press, Athens, Georgia. 575 pp). Adult female *N. domiciliorum* tending eggs will leave their webs up during the day when Green Anoles are active (Edwards, *op. cit.*; Jensen et al., *op. cit.*), which apparently facilitated the lizard's capture in our observation. This is the first report of predation on *A. carolinensis* by *N. domiciliorum* and the first known lizard prey for the spider (G. B. Edwards, pers. comm.).

We thank Lois Stacey for the observation and photograph and G. B. Edwards (Univ. of Florida) for identifying the spider.

JOSEPH C. MITCHELL, Mitchell Ecological Research Service, LLC, P.O. Box 2520, High Springs, Florida 32655-2520, USA (e-mail: dr.joe.mitchell@gmail.com); **CAROL RUCKDESCHEL,** Cumberland Island Museum, P.O. Box 796, St. Marys, Georgia 31558, USA (e-mail: cimuseum@yahoo.com).

***ANOLIS NEBULOSUS* (Clouded Anole). PREDATION.** There are 20 lizard species occurring in seasonally tropical dry forest in the vicinity of Chamela, Jalisco, Mexico. Here we report the first predation record of *Anolis nebulosus* by *Sceloporus melanorhinus* at the Chamela Field Station, Universidad Nacional Autónoma de México, Jalisco (19.497867°N, 105.043047°W). This event was recorded at 1500 h on 7 February, 2010 while using video-cameras (SONY Handy Cam DCR-SX43) to identify potential predators of *A. nebulosus* as part of ongoing research. At our study site, individuals of *A. nebulosus* were attached to a tree with a 50 cm string at a perch height of 25 cm from 900 h to 1500 h for three days, every two months. The video (available upon request) shows one adult *S. melanorhinus* approaching, attacking and consuming an adult *A. nebulosus*. This recorded event lasted 28 seconds and revealed that *S. melanorhinus* is not a strict insectivorous lizard and will feed opportunistically on other smaller lizards. *Anolis nebulosus* is approximately half of the body size of *S. melanorhinus* (43mm SVL vs. 96 mm, respectively) and both species are arboreal, diurnal and insectivorous (Garcia and Ceballos 1994. Guía de Campo de los Reptiles y Anfibios de a Costa de Jalisco, México. [Edición en Inglés y Español]. Fundación Ecológica de Cuixmala, A. C. e Instituto de Biología [UNAM], México. 184 pp.). At Chamela, predation of *A. nebulosus* by *Aspidoscelis lineatissima* also has been recorded occasionally (A. Garcia and B. Lister, pers. obs.). Lizard predation and cannibalism is common in insular *Anolis* species (Gerber 1999. *In* Losos and Leal [eds.], *Anolis* Newsletter V, pp. 28–39. Washington University, Saint Louis, Missouri) but previous records of predation by *Sceloporus melanorhinus* have not been reported before.

We thank the Posgrado en Ciencias Biologicas, UNAM and the Estación de Biología Chamela for faciliation and allowing us to carry out this work.

***ANOLIS SAGREI* (Cuban Brown Anole). AGGRESSIVE BEHAVIOR.** Males of *Anolis sagrei* have a repertoire of aggressive behaviors that they typically use to defend territories, sometimes inflicting considerable injury on an opponent (Henderson and Powell 2009. Natural History of West Indian Reptiles and Amphibians. Univ. Press of Florida, Gainesville. 271 pp.).

From between 1900 and 2000 h on 03 June 2012, I observed three male *A. sagrei* on the road outside of The Island School and Cape Eleuthera Institute on the island of Eleuthera, The Bahamas. One individual (***A***) appeared to be healthy. A second individual (***B***) was dead, but the body was intact showing no obvious physical damage like that which could be caused by vehicular traffic or predatory activity. A third individual (***C***) was alive but relatively immobile and had a severed tail. ***C*** exhibited a dark coloration, which is characteristic of a resident *A. sagrei* in a territorial conflict (Evans 1938. J. Comp. Psychol. 25:97–123). Individual ***A*** was initially positioned next to individual ***B***, but moved several centimeters upon my approach. Once I retreated, ***A*** returned to his position next to ***B***. ***A*** then attacked ***B***, biting and flipping the lifeless body while showing other signs of aggression including tail lashing, a display modifier used during high states of aggressive arousal (Scott 1984. Breviora 479:1–22). When I moved closer to observe the interaction in greater detail, ***A*** moved a short distance toward individual ***C***. When I once again retreated, ***A*** returned and resumed his attack on ***B***. I left and returned ~15 min later, at which time I found ***C*** dead, presumably a result of an attack by ***A***. At this time, ***A*** was once again attacking the body of ***B***. I left the site and returned ~30 min later finding only the lifeless males and a previously unseen female that was walking slowly around the body of ***B***.

Robert Powell and John S. Parmerlee, Jr. reviewed the manuscript and helped edit the images. Sandra D. Buckner and Stacy Lubin-Gray facilitated our fieldwork in the Bahamas and the staff

of the Cape Eleuthera Institute and the Island School was quite tolerant of our antics. The permit to conduct research in the Commonwealth of the Bahamas was issued by Philip S. Weech, Director, The BEST Commission. Protocols were approved by the Avila University Animal Care and Use Committee (IACUC 2007-01). Fieldwork was funded by a grant from the National Science Foundation (USA) to Robert Powell (DBI-0851610).

***ASPIDOSCELIS GULARIS* (Common Spotted Whiptail). CLUTCH SIZE.** *Aspidoscelis gularis* has a wide distribution from southern Oklahoma to Jalisco and Querétaro, Mexico with several recognized subspecies throughout its distribution (Hammerson et al. 2007. *In* IUCN 2012. IUCN Red List of Threatened Species. Version 2012.1. <www.iucnredlist.org>. Accessed on 19 September 2012). Little information is known regarding the reproduction and litter size of this species in the state of Jalisco. In the state of Querétaro, clutch size has been reported as 1–4 eggs, depending on female body size (Dixon and Lemos Espinal. 2010. Anfibios y Reptiles del Estado de Querétaro, México/Amphibians and Reptiles of the State of Queretaro, Mexico. UNAM, ATM and CONABIO. 428 pp.). In Durango, the reported clutch size is 1–5 eggs (Estrada-Rodríguez et al. 2004. Cañón de Fernández: Anfibios y Reptiles. Instituto de Ecología, A.C. Goméz Palacios, Durango, México. 60 pp.). In Zacatecas, a clutch size of 1–7 eggs has been reported, although based on oviductal eggs rather than actual clutches (Walker 1981. Copeia 1981:850–868).

On 26 October 2009, a litter of 8 hatchlings of *Aspidoscelis gularis* was found on Cerro La Mesa, in the town of Temacapulin, in the municipality of Cañadas de Obregon, Jalisco, Mexico (21.199797°N, 102.708274°W, datum WGS84; elev. 1745 m). The recently hatched lizards were healthy, inactive, and all together under a rock in xerophilic scrub, under direct sunlight, on the side of a dirt road. When the rock was lifted, three of them attempted to escape, but were captured to be photographed. We counted 8 hatchlings and found the 8 corresponding fresh egg shells. We did not find any unhatched eggs or extra shells. The hatchlings were returned under the rock where they were found after some photos were taken. This is the first report of litter size for this species in Jalisco and augments data for the subspecies *A. g. semptemvittata*.

FIG. 1. Eight hatchling *Aspidoscelis gularis* from a single litter found in Jalisco, Mexico.

***ASPIDOSCELIS LAREDOENSIS* (Laredo Striped Whiptail). GYNANDROMORPH.** We evaluate the identity and reproductive status of a whiptail lizard specimen collected from a site of syntopy between diploid hybrid-derived *Aspidoscelis laredoensis* and this species' maternal progenitor, *A. gularis* (McKinney et al. 1973. Herpetologica 29:361–366; Bickham et al. 1976. Herpetologica 32:395–399; Wright et al. 1983. Herpetologica 39:410–416) situated in México (Walker 1987. Texas J. Sci. 39:313–334). The lizard stands apart in size and color pattern among the >1000 specimens of these species examined by us between 1984–2009 from México and Texas. It was tentatively identified as a hybrid between these species by Walker et al. (1989a. J. Herpetol. 23:119–130). However, genealogical causation (i.e., fertilization of an unreduced diploid egg of *A. laredoensis* clonal complex A by a reduced sperm of *A. gularis*) was selected without appropriate assessment of the other possible bases (i.e., gynandromorphism, senescence, or a variational outlier involving one of these species) for the observed condition of the reproductive organs and external morphology. Fortunately, we have subsequently examined several live/freshly killed male and female putative hybrids of *A. laredoensis* x *A. gularis* that were subjected to confirmational studies of their genealogies based on triploidy as verified by karyotypes (Walker et al. 1989a, *op. cit.*; Walker et al. 1989b. Copeia 1989:1059–1064) and skin histocompatibility experiments (Abuhteba et al. 2000. Can. J. Zool. 78:895–904; Abuhteba et al. 2001. Copeia 2001:262–266). Morphological studies of these hybrids have also revealed the presence of well-defined character states of dorsal and ventral color pattern, scutellation, and meristic variables that differ from the parental species. In this study we use morphological and histological evidence in support of our identification of a gynandromorph of *A. laredoensis* from México deposited in the Arkansas State University Museum of Zoology (ASUMZ).

On 27 May 1985, we collected 11 specimens of *A. laredoensis* just south of the Rio Grande in the Mexican state of Tamaulipas; University of Arkansas Department of Zoology (UADZ 1101) from the vicinity of the northwest suburbs of Reynosa on Mexican Hwy 102 near a hydroelectric complex, and UADZ 1102–1111 (and one *A. gularis*, UADZ 1260) from La Playita situated 8 km NW of Reynosa. Subsequently, UADZ 1111 became ASUMZ 4654 in preparation for this study. It has a SVL of 86.5 mm, head length of 26 mm, head width of 13.5 mm, and body mass (obtained before preservation) of 13.5 g. It is much larger than any of the other adults of *A. laredoensis* (mean SVL 69.9 ± 0.89, range 66–76 mm, N = 10) collected on the same date at the two sites in Tamaulipas. The SVL and mass of ASUMZ 4654 are 13.2% and 33.3% larger, respectively, than observed in any other individual of *A. laredoensis* from the sites. Based on the size of the lizard, we initially hypothesized that it was an *A. laredoensis* x *A. gularis* hybrid; however, we now know that such lizards have discrete morphological markers not present in ASUMZ 4654. The slightly to moderately enlarged postantebrachial scales (Fig. 1A) of the specimen places it within the range of variation for this character present in the 10 contemporary *A. laredoensis* (slightly to moderately enlarged) rather than that of *A. gularis* (enlarged and plate-like), or a character state intermediate between the two

species. In addition, scores for meristic characters in ASUMZ 4654 (first number) are also within the ranges of variation for the other specimens of *A. laredoensis* from the sites (mean, range, N): granular scales around midbody, 91 (90.4 ± 0.67, 89–94, N = 9); granular scales from occiput to base of tail, 227 (225.2 ± 0.22, 222–229, N = 9), granular scales between the paravertebral stripes, 14 (11.1 ± 0.48, 9–14, N = 9); right and left femoral pores summed, 33 (34.1 ± 0.31, 31–35, N = 10); and right and left circumorbital scale series summed, 12 (10.3 ± 0.33, 9–12, N = 10).

Based on SET field notes made shortly after collection, and prior to preservation, ASUMZ 4654 possessed color attributes that we subsequently learned should have precluded identification of it to either *A. gularis* or *A. laredoensis* x *A. gularis*, the overall resemblance being that of an unusually old individual of *A. laredoensis* that had progressed to an extreme color pattern ensemble. Included was a blue face, blue-green dorsal surface of head, and light blue throat and mesoptychium, with no evidence of pink or red hues typical of either *A. gularis* or all known adult hybrids between the two species. The dorsal pattern in ASUMZ 4654 consisted of three pairs of moderately (lateral) to well-defined (dorsolateral and paravertebral) primary stripes and a single vertebral (traits of *A. laredoensis*; Fig. 1B). In life, the green-hued stripes were positioned between brown-black fields suffused with green flecks; the stripes ended near the tail. Using the left side of the body for analysis, we noted sixteen partial to complete gray-green-tan vertical bars in the lower lateral field, 22 rounded spots of the same blend of colors in the upper lateral field, and a series of three similarly colored spots in the

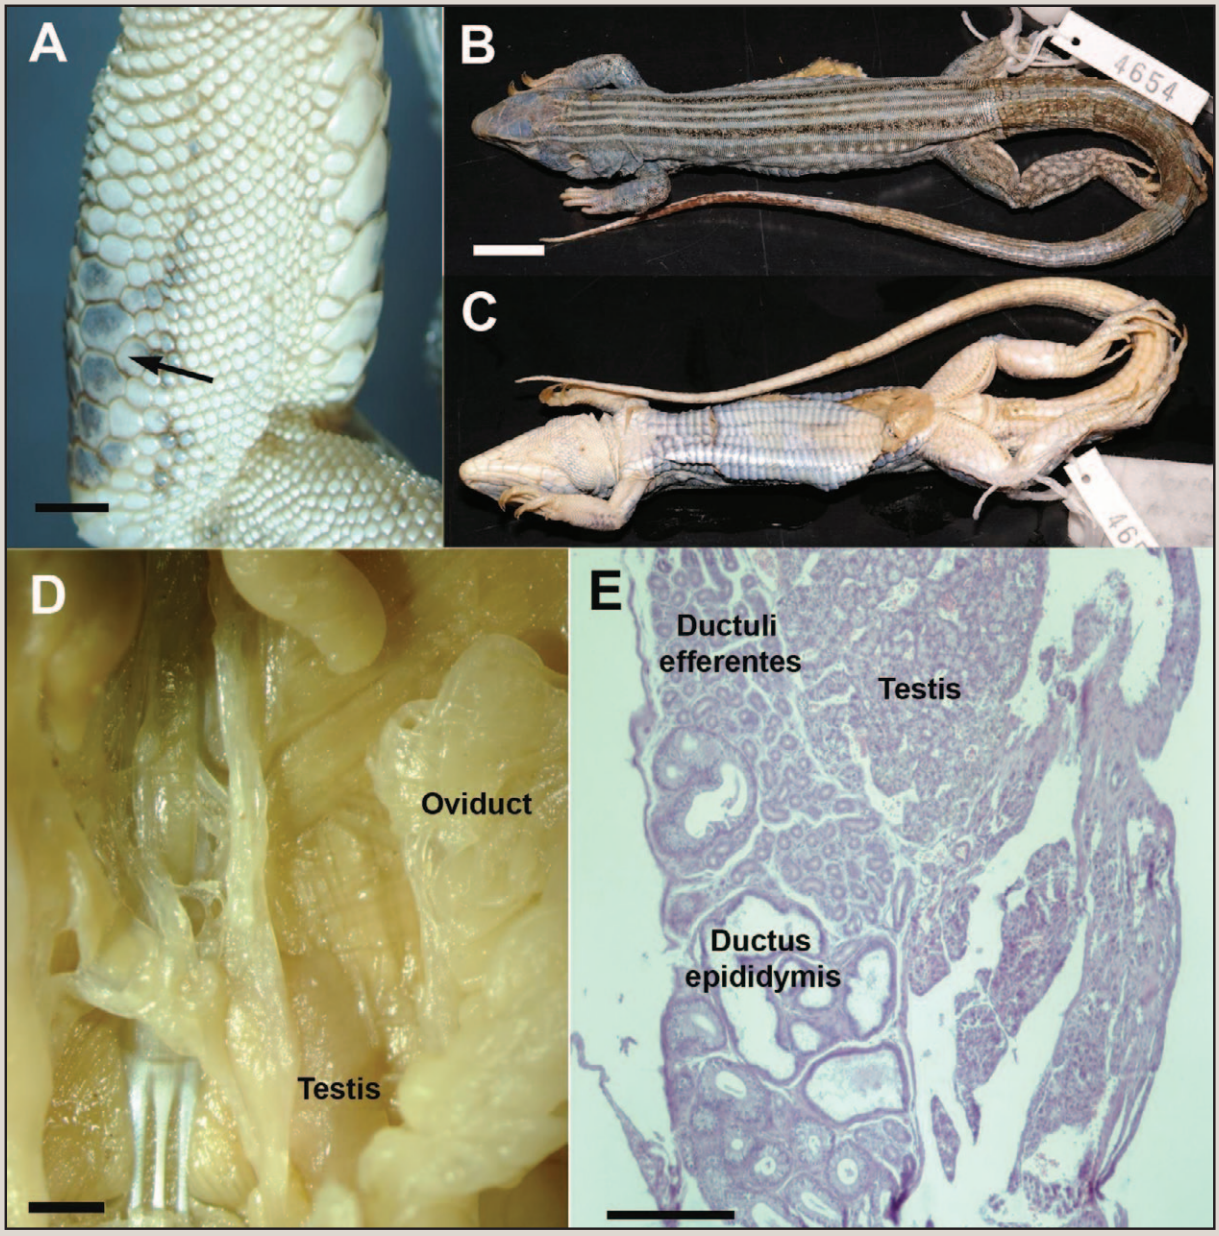

FIG. 1. Morphological characteristics of a gynandromorph of *Aspidoscelis laredoensis* (ASUMZ 4654) collected from La Playita, Tamaulipas, México. A) Postantebrachial scales (arrow) of right antebrachium; line = 1 mm. B) Dorsal coloration and pattern; line = 10 mm for B and C. C) Ventral coloration. D) Left gonadal structures; line = 1 mm. E) Longitudinal histosection of left testis and ductus epididymis; line = 200 µm.

dorsolateral field near the tail. Some of the spots and bars of the upper and lower lateral fields, respectively, were fused to or superimposed upon the lateral stripes (Fig. 1B). The tail was blue laterally and olive dorsally. The upper parts of forelimbs were hues of green and the forearms were shades of blue, both areas with indistinct gray-white marking. The hindlimbs were olive dorsally, and shades of blue elsewhere, with gray-white markings. The thoracic and abdominal scales were sky blue, some with darker edges. The ventral surfaces of the limbs and tail were a mixture of blue and cream-white (Fig. 1C).

We used a standard histological protocol to prepare reproductive tissues for light microscopy. Gonadal tissues were dehydrated in a graded series of ethanol, cleared in xylene, embedded in paraffin, sectioned with a rotary microtome into 10 µm sections, stained with Harris hematoxylin and counterstained with eosin. We designated this lizard to be a gynandromorph due to the presence of an abnormal sexual anatomy characteristic of both sexes. No ovaries were observed; however, paired Müllerian ducts (oviducts) of moderate development were positioned lateral to small (< 5 mm in length), paired rudimentary gonads (Fig. 1D). These gonadal structures appeared slightly orange in coloration upon gross inspection. Histological examination of the left gonadal mass (Fig.1E) revealed a differentiated ovoid testicular mass immediately adjacent to numerous mesonephric derivatives including efferent ductules of the ductuli efferentes and a ductus epididymis with ductules of variable size and epithelial height. Adrenal tissue was aggregated along the cauda of the epididymis (Fig. 1E). The testicular mass, enveloped by a thin connective tissue tunic, was organized into tightly packed medullary cords (Fig. 1E) that appeared to be precursors to seminiferous tubules. These cords averaged 35.3 µm in diameter (range, 31.6–43.3 µm; N = 10). The germ cells of the cords did not appear to be mitotic. The cytoplasm of the germ cells of the cords was slightly basophilic throughout the testicular mass. Numerous blood vessels were interspersed among these presumptive seminiferous tubules, and the tubules generally lacked lumina. Numerous spherical efferent ductules were dispersed along the entire medial margin of the testicular mass. Those ductules adjacent to the caudal region of the testicular mass (Fig. 1E) averaged 40.2 µm in diameter (range, 33.3–48.3 µm; N = 10). The low simple columnar epithelia of these ductules exhibited stereocilia, and the apical cytoplasms of these cells were slightly acidophilic.

The cauda portion of the epididymis was more developed than either the caput or the corpus, which were poorly organized. The anteriormost mesonephric ductules of the cauda exhibited simple columnar epithelia that averaged 27.3 µm in height (range 20.0–36.0 µm; N = 10). The epididymal duct within the cauda exhibited irregular, greatly-expanded segments (Fig. 1E). These hypertrophied ductal tubules exhibited a low simple columnar epithelium (Fig. 1E) with the epithelial cell layer averaging 11.5 µm in height (range 9.8–14.6 µm; N = 10) in height. The epithelial cells also exhibited conspicuous stereocilia averaging 12.6 µm in height (range 10.3–14.6 µm; N = 10). Finally, acidophilic cellular debris was observed in epididymal ductules leading to the ductus deferens.

This is only the second publication known to us in which terminology specifically in reference to gynandromorphism has been employed to describe the reproductive organs in a specimen of a whiptail lizard species. Mitchell and Fouquette (1978. Copeia 1978:156–159) described an adult (Arizona State University 15323; 67 mm SVL) of *Cnemidophorus inornatus arizonae* (= *Aspidoscelis inornata arizonae* sensu Reeder et al. 2002. Am. Mus. Novit. 3365:1–61) collected 10 July 1975 from 7 km SE of Willcox, Cochise Co., Arizona, with male reproductive organs in the left side of the body cavity and female organs in the right side of the cavity. These authors, albeit based on morphology, explicitly rejected the hypothesis that the specimen in question was a tetraploid hybrid involving triploid *A. uniparens* which was also present at the Arizona site. More recently, Cole et al. (2010. Am. Mus. Novit. 3698:1–43) chose to use the terminology "apparently female (but intersex) laboratory hybrid" to describe a genetically confirmed allodiploid individual (American Museum of Natural History 153158; 81 mm SVL) of *A. inornata arizonae* () x *A. tigris marmorata* ().

CORDES**, Division of Sciences and Mathematics, Louisiana State University Eunice, Eunice, Louisiana 70535, USA (e-mail: jcordes@lsue.edu).

***BRACHYLOPHUS BULABULA* (Fiji Banded Iguana). PREDATION.** Documented predation of any South Pacific iguana is rare, as all three species remain very uncommon and restricted in range. Two previous studies have reported food habits of wild Pacific Boas (*Candoia bibroni*), and neither found evidence of these boas preying on *Brachylophus* (McDowell 1979. J. Herpetol. 13:1–92; Harlow and Shine 1992. J. Herpetol. 26:60–66). One

COLOR REPRODUCTION SUPPORTED BY THE THOMAS BEAUVAIS FUND

FIG. 1. *Candoia bibroni* preying on *Brachylophus bulabula* on Wakaya Island, Fiji.

second-hand account (Gibbons and Watkins 1982. *In* Burghardt and Rand [eds.], Iguanas of the World, pp. 418–441. Noyes Publ., Park Ridge, New Jersey) reported that a *B. fasciatus* was observed being eaten by a *C. bibroni* on Vanuabalavu Island in Fiji. We report here a verified observation of predation on *B. bulabula* by a *C. bibroni* (Fig. 1.) on Wakaya Island in Fiji (17.60°S, 179.00°E) from 17 October 2008. The predation event involved an adult *B. bulabula*, being consumed by an adult *C. bibroni*. Adult *B. bulabula* weigh approximately 125 g (RNF, unpubl. data), making this iguana a significantly larger prey item than skinks and geckos, which are reported to constitute most of the diet for *C. bibroni* (McDowell, *op. cit.*; Harlow and Shine, *op. cit.*).

Candoia and *Brachylophus* are known to co-occur on many islands in Fiji (Fisher and Harlow, unpubl. data), although the island with the highest known density of *Brachylophus* iguanas apparently lacks *Candoia* (Harlow and Biciloa 2001. Biol. Conserv. 98:223–231). It is possible there is a previously undocumented top down effect of these snakes on iguanas when they co-occur on small islands.

ROBERT N. FISHER, U.S. Geological Survey, San Diego Field Station, 4165 Spruance Road, Suite 200, San Diego, California 92101-0812, USA (e-mail: rfisher@usgs.gov); **PETER THOMSON**, Permanent Mission of the Republic of Fiji to the United Nations, New York, New York, USA; **DICK WATLING**, NatureFiji-MareqetiViti, P.O. Box 2041, Government Buildings, Suva, Fiji (e-mail: watling@naturefiji.org); **PETER S. HARLOW**, Taronga Conservation Society Australia, PO Box 20, Mosman, NSW, Australia (e-mail: pharlow@zoo.nsw.gov.au).

***CROTAPHYTUS COLLARIS COLLARIS* (Eastern Collared Lizard). FRUGIVORY.** Lizards of the genus *Crotaphytus* are commonly viewed as being strictly carnivorous, feeding mainly on insects and occasionally on small vertebrates (McGuire 1996. Bull. Carnegie Mus. Nat. Hist. 32:1–143). However, in May 2011, one of us (JJC) observed an individual *Crotaphytus collaris* ingesting *Morus* sp. fruit. The observation was made during a two-year study of the behavioral ecology of *C. collaris collaris* in the Smoky Hills region of central Kansas, USA. The individual was an adult male, perched within a ~1 m *Morus* sp. tree. Our observation constitutes the first documentation of frugivory in *C. collaris* in the northeastern portion of its range, as well as the first documentation of any crotaphytid ingesting *Morus* sp. fruit. Literature discussing the diet of crotaphytid lizards reference occasional herbivory (Best and Pfaffenberger 1987. Southwest. Nat. 32:415–426; Blair and Blair 1941. Am. Midl. Nat. 26:230–232; Ellis and Henderson 1913. Univ. Colorado Stud. 10:39–129; Fitch 1956. Univ. Kansas Publ. Mus. Nat. Hist. 8:213–272), and frugivory is noted specifically in three reports (Banta 1960. Wasmann J. Biol. 18:309–311; Montanucci 1971. Herpetologica 18:183–197; Turner et al. 1969. Herpetologica 25:247–257). These reports note ingestion of *Lycium* sp. fruit by *C. bicinctores* (as *C. collaris baileyi*) in southern Nevada (Banta 1960, *op. cit.*), *C. reticulatus* in southern Texas and northern Mexico (Montanucci 1971, *op. cit.*) and *Gambelia wislizenii* (as *C. wislizenii*) in southern Nevada (Turner 1969, *op. cit.*). Collectively, these observations suggest fruit might be a standard dietary component of crotaphytid lizards throughout their geographic range, despite the traditional view of crotaphytids as strictly carnivorous.

KATHERINE M. TALBOTT (e–mail: kmtalbott@mail.fhsu.edu) and **JEFFREY J. CARTER**, Fort Hays State University, Department of Biological Sciences, 600 Park Street, Hays, Kansas 67601, USA.

***DRACO QUINQUEFASCIATUS* (Five-banded Gliding Lizard). REPRODUCTION.** *Draco quinquefasciatus* inhabits lowland rainforest particularly in peat swamp forest. It forages on tree trunks looking for ants, termites and small insects. This gliding lizard is widely distributed from Trang in southern Thailand to Peninsular Malaysia, Sumatra and Borneo (Cox et al. 1998. A Photographic Guide to Snakes and other Reptiles of Peninsular Malaysia, Singapore and Thailand. New Holland Publishers, UK. 144 pp.). The total length of this species is up to 27 cm and the female can lay up four eggs per clutch (Cox et al. 1998, *op. cit.*). A clutch of two eggs (measuring 16.8 and 17.2 mm) were reported as obtained from the buttress leaf litter within a dipterocarp forest (Das 2007. A Pocket Guide of Amphibians and Reptiles of Brunei. Natural History Publications [Borneo], Kota Kinabalu, Sabah. 200 pp.). Here I report on a maximum clutch size for *D. quinquefasciatus*.

On 11 February 2011, between 2100 and 2200 h, an adult female *D. quinquefasciatus* was caught at Sungai Sedim (5.250574°N, 100.465147°E; elev. < 200 m), Kedah, Malaysia. This specimen was captured while perching on a tree trunk (ca. 3–4 m above ground). For further inspection, the lizard was euthanized and dissected and four whitish eggs in the uterus were found. The oval-shaped eggs were measured and the mean ± SD (range, N) length, diameter and weight of the eggs were 14.5 ± 0.58 mm (14–15, 4), 7.5 ± 0.58 mm (7–8, 4) and 601 ± 13.6 mg (587–615, 4), respectively. Later the specimen (11USM-SDM-DQ01) was fixed with 10% formalin, stored in 70% ethanol and deposited at School of Pharmacy, Universiti Sains Malaysia for reference.

I extend heartfelt gratitude to Universiti Sains Malaysia, Penang for all the facilities and amenities provided. This project was funded by USM, Research University Grant No. 1001/PFARMASI/811156.

SHAHRIZA SHAHRUDIN, School of Pharmaceutical Sciences, Universiti Sains Malaysia, 11800 Penang, Malaysia; e-mail: shahriza20@yahoo.com.

***ENYALIUS BRASILIENSIS*. DEATH-FEIGNING.** *Enyalius brasiliensis* is an Atlantic forest species of Brazil, inhabiting areas with humid vegetation and closed canopies (Jackson 1978. Arq. Zoo. 30:1–79). Almost nothing is known about the ecology of the genus *Enyalius* and information available is restricted to accounts of feeding habits and microhabitat use (Jackson, *op. cit.*; Sousa et al. 2008. Iheringia Sér. Zool. 98:260265; Van Sluys et al. 2004. Braz. J. Biol. 64:353–356; Vanzolini 1972. Pap. Avulsos Zool.

FIG. 1. Death-feigning posture in a female *Enyalius brasiliensis*.

26:83–115; Vitt et al. 1996. Herpetol. Nat. Hist. 4:77–82; Zamprogno et al. 2001. Rev. Bras. Biol. 61:91–94). Little information is published on behavioral aspects of this species.

Death-feigning, also known as tonic immobility or thanatosis, is an innate, anti-predator behavior. In squamates, death-feigning is a widespread defensive tactic that is described from several different families, such as Anelytropsidae (Torres-Cervantes et al. 2004. Herpetol. Rev. 35:384), Crotaphytidae (Gluesing 1983. Copeia 1983:835–837), Scincidae (Langkilde et al. 2003. Herpetol. J. 13:141–148), and Tropiduridae (Bertoluci et al. 2006. Herpetol. Rev. 37:472–473; Machado et al. 2007. S. Am. J. Herpetol. 2:136–140). Herein we provide observations on death-feigning in *Enyalius brasiliensis* with a brief description of the behavior in this lizard.

We collected two *E. brasiliensis* specimens during the inspection of a drift fence with pitfall and funnel traps used for a reptile survey conducting inventory of the area sampled. Both lizards exhibited death-feigning when removed from the traps and when manipulated in the laboratory to perform marking procedures and/or morphometric analysis. On 29 September 2008 we collected a male *Enyalius brasiliensis* (SVL: 74.7 mm), and on 31 October 2009 we collected a female of *E. brasiliensis* (SVL: 102.3 mm) in fragmented forest of Atlantic Rainforest in the Floresta Farm (21.742667°S, 43.29225°W, WGS 84; ca. 709 m elev.), in the municipality of Juiz de Fora, State of Minas Gerais, Brazil. The lizards became immobile, lying belly-up, crossing the limbs over the stomach and typically closing the eyelids. The death-feigning posture persisted even after the animal was gently placed upside down on the ground (Fig. 1). An individual would recover after 15–30 min and then attempt to flee. Both specimens were deposited in the Coleção Herpetológica da Universidade Federal de Juiz de Fora (CHUFJF 586, 591). We believe these observations to be the first records of death-feigning in this lizard species..

We thank C. H. V. Rios and W. L. Ouverney Jr. for field assistance and T. M. Machado for valuable suggestions on the manuscript. We thank a grant from the Cordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES) for the financial support and also IBAMA for the authorization for animal capture issued under the number 17074-1.

***HELODERMA SUSPECTUM* (Gila Monster). FEMALE REPRODUCTIVE ANATOMY.** Variation in gross uterine morphology is well defined in mammals (i.e., Kobayashi and Behringer 2003. Nature Rev. Genet. 4:969–980), and has been included in comparative anatomy textbooks for decades. In placental mammals the uterus has been described as duplex, bicornuate, bipartite, or simplex (Koayashi and Behringer 2003 *op. cit.*). However, until recently (e.g., Siegel et al. 2011a. J. Anat. 218:342–348; Siegel et al. 2011b. Acta Zool. 93:400–408), little attention has been paid to the variation in female reproductive anatomy of reptiles, and even this recent literature failed to describe multiple "types" of uteri similar to those described in mammals. From Gadow (1887. Phil. Trans. R. Soc. Lond. B. 178:5–37) and Gabe and Saint-Girons (1965. Mem. Mus. Nat. Hist. XXXIII:149–332), all lepidosaurs, testudines, and crocodylians possess paired uteri that empty into the cloaca separately. Thus, it would appear that all non-mammalian amniotes possess uterine morphology that is most similar to the "duplex" condition described for some mammals; although Gadow (1887, *op. cit.*) does mention the possible fusion of uteri in a lizard of the genus *Lophura* (no species provided), which we can only assume is a synonym for *Hydrosaurus* (sailfin lizards).

In a broad survey of squamate urogenital tracts, in-depth literature review, and histological preparation of cloacal/oviducal junctions from hundreds of squamate individuals (Siegel et al. 2011a, *op. cit.*; Siegel et al. 2011b, *op. cit.*), we found the dogma of non-mammalian amniotes possessing only duplex-like uteri to be correct in all but one species: *Heloderma suspectum* (Gila Monster). Tissues from the cloacal/oviducal junction of two preserved *H. suspectum* specimens were obtained from the Sam Noble Oklahoma Museum of Natural History (#020151 and #32499). Tissues were dehydrated with ascending concentrations of ethanol, cleared in toluene, embedded in paraplast, serially sectioned at 10 µm, affixed to albumenized slides, and stained with hematoxylin and eosin for general histological examination.

At the cranial aspect of the cloaca, paired uteri can be observed traveling dorsal to the urodaeal chamber (Fig. 1A). As the

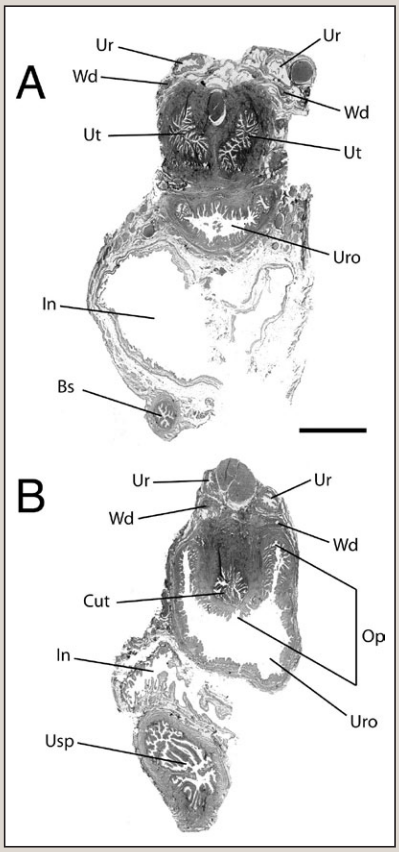

FIG. 1. Cross sections from the cloacal/oviducal junction of female *Heloderma suspectum* (hematoxyline and eosin; scale bar = 2,800 µm). Please see Siegel et al. (2011c. Reproductive Biology and Phylogeny of Snakes. CRC Press, Boca Raton. 759 pp.) for a review of cloacal anatomy and terminology in squamates. **A.** Paired uteri residing dorsal to the cranial aspect of the urodaeum. **B.** A common uterus resulting from the union of the paired uteri. Bs, bladder stalk; Cut, common uterus; In, intestine; Op, oviducal papilla; Ur, ureter; Uro, urodaeum; Usp, urodaeal sphincter; Ut, uterus; Wd, Wolffian duct.

uteri persist caudally, the urodaeal chamber enlarges (Fig. 1B). Paired uteri then invade the enlarged urodaeal chamber and unite forming a single large oviducal papilla (Fig. 1B). At this level the lamina propria of each uterus merges with that of the urodaeum. Immediately caudal to the uterine-cloaca junction, the epithelia of each uterus join and create a common uterine opening into the urodaeum at the most caudal aspect of the uterus (Fig. 1B). The union of the uteri occurs at the posterior, non-glandular portion of the uterus (region 2, see Siegel et al. 2011c. Reproductive Biology and Phylogeny of Snakes. CRC Press, Boca Raton. 759 pp.). Thus, female *Heloderma suspectum* possess a bipartite-like uterus.

The basal lineage of Lepidosauria (i.e., *Sphenodon*; Meyer and Zardoya 2003. Annu. Rev. Ecol. Evol. Syst. 34:311–388) possesses a duplex-like uterus (Gabe and Saint-Girons 1965, *op. cit.*). Because no mammalian amniote possesses a cloacal/oviducal junction (i.e., these taxa have a vaginal/oviducal junction instead) besides the basal Monotremata (Meyer and Zardoya 2003, *op. cit.*), and monotrematan taxa do not possess bipartite uteri (Kobayashi and Behringer 2003, *op. cit.*), the bipartite-like uterus in a non-basal lineage of Lepidosauria is secondarily derived. We make no hypothesis of similar function between the bipartite-like uterus of *Heloderma suspectum* and the bipartite uterus of mammals, but suggest that the bipartite-like uterus is a convergent characteristic. Female specimens of *Hydrosaurus* (see Gadow 1887, *op. cit.*) should be examined to elucidate the possibility of a similar bi-partite uterus in another lineage of lizards (e.g., Agamidae).

***HEMIDACTYLUS BRASILIANUS* (Amaral's Brazilian Gecko). DIET.** *Hemidactylus brasilianus* is nocturnal with terrestrial/arboreal habits (Rodrigues 2003. *In* Ecologia e Conservação da Caatinga, pp. 181–236. Editora Universitária da UFPE, Recife, Pernambuco; Vanzolini et al. 1980. Répteis das Caatingas. Acad. Bras. de Ciênc., Rio de Janeiro, Brazil. 161 pp.). Few studies have been conducted on the diet of *H. brasilianus* (Rocha and Rodrigues 2005. Pap. Avul. Zool. 45:261–284). Thus, the aim of the present study was to assess the food composition of *H. brasilianus* in a caatinga region of the San Francisco Valley, northeastern Brazil.

Collections were conducted from 19 September to 5 November, 2011 during a herpetology course in an area of bushy caatinga (9.3280°S, 40.5497°W; elev. 385 m) on the Agrarian Sciences Campus of the Universidade Federal do Vale do São Francisco – UNIVASF, Petrolina, Pernambuco, Brazil. Lizards were captured in pitfalls (7-liter buckets). In the lab, individuals were euthanized with an injection of xylocaine diluted in water. Stomach contents were analyzed under stereomicroscope to identify the food items ingested, most taxa to order level. Larval stages of the orders Lepidoptera and Coleoptera were assigned to the same prey category (insect larvae) because they represent a single morphotype.

Diet was analyzed from numerical (occurrence and numerical frequencies of ingested items) and volumetric data. The volume (V) of food items was estimated using the modified version of the spheroid formula: $V = 4/3\varpi\ (width/2)^2 \times (length/2)$, following Vitt et al. (1996. J. Trop. Ecol. 12:81–101). To calculate food niche breadth from numerical proportions and remove the effect of the number of prey categories consumed, we used standardized values of Simpson's Diversity Index in the equation of Levin's Standardized Index, as follows: $B_a = B - 1/n - 1$, where B is Simpson's niche breadth index, and n the number of prey categories used. Values in this case range from 0 (exclusive use of a single prey category) to 1 (equal use of all prey categories) (Kenney and Krebs 2000. Programs for Ecological Methodology. Version 5.2. Vancouver, Canada. University of British Columbia). Moreover, the importance value index (IVI) was calculated to determine the proportion of each diet item, adding occurrence, numerical and volumetric percentages, and dividing by three (*IVI=F%+N%+V%/3*) (Mesquita et al. 2006. Copeia 2006:460–471). Grouped stomach contents, and separating males and females, were considered in this analysis. The Mann-Whitney U test was applied to determine possible differences in snout-vent length between males and females.

A total of 11 individuals were collected, seven males, three females and one whose sex was not identified. The SVL of males (35.1 ± 6.5 mm) did not differ significantly from that of females (42.4 ± 6.3 mm) (Mann-Whitney U test, Z = -1. 481, P = 0. 138). With respect to diet, five categories of consumed prey were recorded for *H. brasilianus* (Table 1). The highest occurrence frequencies were registered for insect larvae (45.5%) and Blattaria (36.4%), but numerically, termites (Isoptera) were the most important items (52.6%). Despite the considerable consumption of Isoptera, in terms of volume, Blattaria was the most important food item consumed (34.4%) (Table 1).

The largest importance index value was recorded for insect larvae (33.4), followed by Isoptera. Considering sex, we found an absence of Isoptera in the diet of *H. brasilianus* males and a high importance index for insect larvae (48.3). For females, the highest importance index values were for Isoptera (66.2) and insect larvae (19.6); however, it is important to underscore that only one female consumed a large amount of termites, skewing the importance value for this category.

Prey categories consumed show that *H. brasilianus* predominantly captures nocturnal prey (cockroaches and crickets), with little mobility (insect larvae) and unpredictable, aggregate distribution (termites). Insect larvae, represented by the highest IVIs (total, for males, and second for females), were also important items in the diet of *H. brasilianus* in a dune field belonging to the Caatinga of Bahia state (Rocha and Rodrigues, *op. cit.*). We believe that this marked consumption of insect larvae is associated with their wider availability in the study area. However,

TABLE 1. Diet composition of *Hemidactylus brasilianus* at Campus Ciências Agrárias, Petrolina municipality, Pernambuco, Brazil, from September to November 2011. F = frequency of occurrence, N = number, V = volume (mm^3), IVI = importance value index (t = total sample, m = males, f = females).

Prey category	F (%)	N (%)	V (%)	IVIt	IVIm	IVIf
Blattaria	4 (36.4)	4 (10.5)	360.8 (34.4)	27.1	36.9	14.2
Coleoptera	1 (9.1)	1 (12.6)	67.0 (6.4)	6.0	10.2	–
Isoptera	1 (9.1)	20 (52.6)	209.3 (20.0)	27.2	–	66.2
Insect larvae	5 (45.5)	10 (26.3)	296.7 (28.4)	33.4	48.3	19.6
Orthoptera	3 (27.3)	3 (8.0)	112.5 (10.8)	15.4	18.9	–
TOTAL		38	1,046.3			

the food niche breadth of *H. brasilianus* (0.437) reveals moderate diet specialization, and despite the small number of prey types, food resource exploitation is relatively equitable. In addition, these findings are correlated with behavioral characteristics of *H. brasilianus,* such as its nocturnal habits and arboreal lifestyle, with only sporadic activity at ground level.

The *H. brasilianus* specimens (CCA 007, 013, 018, 022, 025, 028, 029, 033, 055, 057 and 058) were deposited in the Herpetological Collection of the Caatinga Fauna Museum at CEMAFAUNA-CAATINGA (Centro de Conservação e Manejo de Fauna da Caatinga). We thank the CEMAFAUNA-CAATINGA for logistical support and the Chico Mendes Institute for Biodiversity Conservation (ICMBio) for issuing the collection license (n° 29558-1).

***LEPIDODACTYLUS LUGUBRIS* (Mourning Gecko). REPRODUCTION.** *Lepidodactylus lugubris* occurs in most parts of Oceania and has been introduced into parts of Asia and North, Central and South America (Kraus 2009. Alien Reptiles and Amphibians A Scientific Compendium and Analysis. Springer Science. 563 pp.). It is an all-female parthenogenetic species that originated due to hybridization (Yamashiro et al. 2000. Zool. Sci. 17:1013–1020). However, males, which are generally considered to be the consequences of crosses between *L. lugubris* females and males of congeneric bisexual species, are occasionally found (Röll et al. 2008. Zoology 111:385–400) and have been reported from Hawaii and the Ryukyu Archipelago (Brown and Murphy-Walker 1996. Herpetol. J. 6:69–73; Yamashiro and Ota 1998. Jpn. J. Herpetol. 17:152–155). The purpose of this note is to report a second phenotypic male *L. lugubris* from Hawaii, USA.

One male *L. lugubris* (SVL = 48 mm), collected 12–15 August 1998, at Hilo, district of South Hilo, Hawaii, Hawaii USA, and deposited in the herpetology collection of the Natural History Museum of Los Angeles County, Los Angeles, California, USA as LACM 145408, was examined. The testes were removed, embedded in paraffin, sections were cut at 5µm and mounted on glass slides, and stained with hematoxylin followed by eosin counterstain.

The testes of our male *L. lugubris* contained seminiferous tubules of normal morphology (Fig. 1), and contained mainly Sertoli cells, spermatogonia, primary spermatocytes, spermatids and clusters of abnormal sperm, which lacked tails (Fig. 2). Because the spermatozoa lacked tails, we conclude this male was infertile. The histology was similar to that of a phenotypic male *L. lugubris* reported by Röll et al., *op.cit.* The prevalence of male phenotypes in our *L. lugubris* sample from Hilo, Hawaii was 1/20 (5%). This is the second record of a phenotypic male *L. lugubris* from Hilo, Hawaii. In another examination, one of seven (14%) *L. lugubris* collected in May 1986 was also a phenotypic male (Brown and Murphy-Walker op. cit.). Currently, no other *Lepidodactylus* species is known to occur in Hawaii, so these findings tend to suggest that sterile males do occur at very low prevalences in wild populations of *L. lugubris* from Hawaii. Histology slides were deposited in LACM.

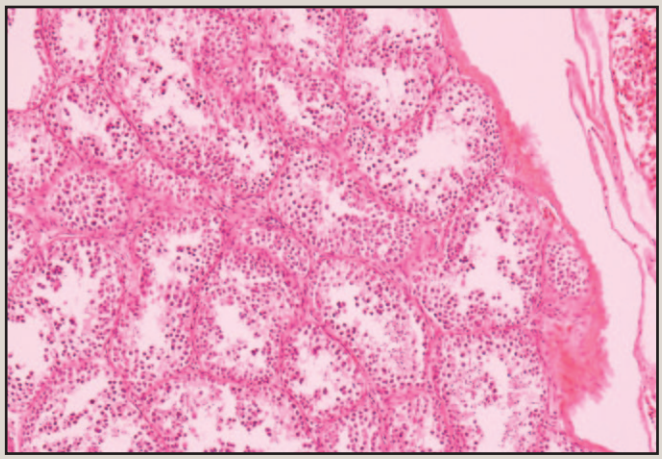

FIG. 1. Seminiferous tubules of the male *Lepidodactylus lugubris* (LACM 145408) described herein. 100x.

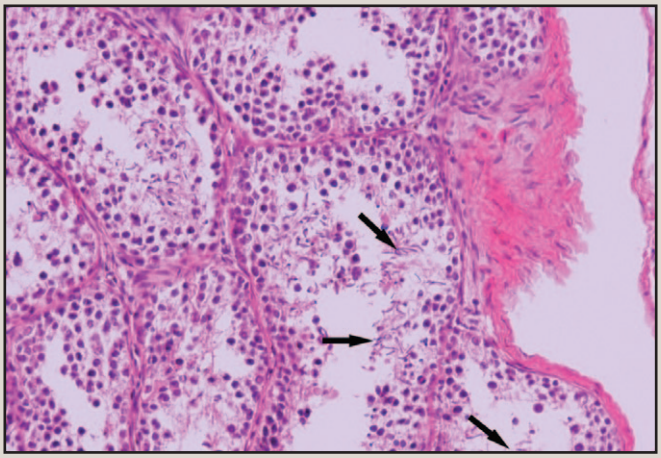

FIG. 2. Seminiferous tubules of the male *Lepidodactylus lugubris* (LACM 145408) described herein. Note the clusters of sperm (arrows) 200x.

We thank G. Pauly (LACM) for permission to examine *L. lugubris*.

***LIOLAEMUS KOSLOWSKYI*. SCOLIOSIS AND KYPHOSIS.** Scoliosis and kyphosis have been recorded in captive lizards (Otero Llende and Bengoa Rodríguez 2001. Res. VII Cong. Anual Soc. Española Med. Veterinaria 1:24–30), but infrequently reported in wild populations of lizards (Chavez-Cisneros and Lazcano 2012. Herpetol. Rev. 42:140; Frutos et al. 2006. Herpetol. Rev. 37:468–469; Mitchell and Georgel 2005. Herpetol. Rev. 36:183–184; Norval et al. 2010, Herpetol. Rev. 41:224–225). Here we provide the first report of scoliosis and kyphosis in *Liolaemus koslowskyi*, a small liolaemid lizard of western Argentina.

On 10 February 2012, we caught an adult female *Liolaemus koslowskyi* (42 mm SVL) on the roadside of Ruta Nacional 40, Cuesta de Miranda, 3.5 km W Bordo Atravesado, near Los

FIG. 1. Adult female *Liolaemus koslowskyi* showing multiple kyphosis and scoliosis.

FIG. 2. X-ray images of adult female *Liolaemus koslowskyi*, lateral (left) and dorsal (right) views.

Tambillos, 2 km NE El Siciliano, Departamento Felipe Varela, La Rioja Province (34.41500°S, 68.80727°W, WGS84; 1664 m elev.). She exhibited two vertical curvatures on the spine (kyphosis), one behind the head in the pectoral girdle and one over the pelvic girdle. In addition, the tail had nine alternating lateral curves (scoliosis) (Figs. 1, 2). This lizard appeared to experience no obvious limitations in mobility. Apparently, these malformations do not appear to decrease the probability of survival of the lizard (Frutos et al., *op. cit.*). To our knowledge, this is the first reported occurrence of these conditions in *Liolaemus koslowskyi* in natural conditions. Voucher specimen (LJAMM 14800) was deposited in the herpetological collection LJAMM-CNP of the Centro Nacional Patagónico (CENPAT-CONICET), Puerto Madryn, Argentina.

***OPHIODES STRIATUS* (Glass-lizard). MINIMUM BODY MASS FOR NEONATES.** *Ophiodes striatus* is an anguid lizard with a cylindrical and elongate body, lacking front limbs, but expressing vestigial hind limbs and is viviparous (Cunha 1961. Bol. Mus. Para. Emilio. Goeldi. Cienc. Nat. 39:1–189). This species is widely distributed, occurring from the montane areas of southeastern and central Brazil, the Cerrado biome and altitude camps in the Atlantic Forest and Araucaria Forest (Barbosa et al. 1991. Rev. Bras. Biol 51:285–287).

On 3 December 2011 an adult female *O. striatus* (CRLZ 000329; body mass = 15.50 g; snout–vent length [SVL] = 18.35 cm; total length [TL] = 29.98 cm) was collected from the Reserva Biológica Unilavras Boqueirão (RBUB) (21.34638°S, 44.99083°W, 1250 m elev.; datum WGS84) in riparian forest associated with phytophysiognomies of Cerrado. The specimen was placed in a terrarium with sandy soil, water, rocks, and natural vegetation obtained at the collection site. Two days later on 5 December 2011, this female gave birth to four young, for which body mass, SVL, and TL were measured. They were then euthanized and fixed in 10% formalin and preserved in 70% alcohol, labeled and deposited in CRLZ. Mean body size of offspring was obtained (body mass = 0.64 ± 0.05 g; SVL = 5.43 cm ± 0.09; TL = 12.80 cm ± 0.20). Prior to this report, morphometric data and body mass of *O. striatus* neonates have not been described. Only data regarding young still within the uterus of females necropsied have been provided until now (Barbosa et al., *op. cit.*; Barros e Teixeira 2007. Bol. Mus. Mello Leitão 22:11–23; Leitão 1973. Iheringia 42:34–39). This study is the first report of minimum body mass for neonates of *Ophiodes striatus*.

This work was licensed by IBAMA (Process n° 14740-1).

***OPHIODES STRIATUS* (Striped Worm Lizard). BIFURCATED TAIL.** Many morphological malformations have been reported on duplication (i.e., bifurcation; trifurcation) of the regenerated portion of the tail in lizards capable of caudal autotomy (see Chan et al. 1984. Hawaii Volcanoes National Park: Proceedings of the Fifth Conference of National Science, pp. 41–50; Chandra and Mukherjee 1980. J. Bombay Nat. Hist. Soc. 77:343; Gogliath et al. 2012. Herpetol. Rev. 43:129; Kumbar and Ghadage 2011. Herpetol. Rev. 42:94; Mata-Silva et al. 2010. Herpetol. Rev. 41:352–353). Generally this duplication is caused by regeneration failure of the tail rather than congenital malformations (Lynn 1950. Herpetologica. 6:81–84).

FIG. 1. Photograph showing a female *Ophiodes striatus* and bifurcated tail. Note the different design pattern of the regenerated tails in relation to the body.

On 9 June 2011, an adult female *Ophiodes striatus* was found on the campus of Juiz de Fora Federal University, in the municipality of Juiz de Fora, Minas Gerais, Brazil (21.773698°S, 43.368405°W, WGS84; 857 m elev.) with an unusual double tail (Fig. 1). It weighed 24.7 g and measured 111.50 mm (SVL). The main tail measured 90.41 mm and the bifurcated portion measured 48.94 mm. Most lizard species can regenerate broken tails, but the regenerated part usually differs in shape and color from the original tail; this specimen expressed a uniformly colored tail, lacking the striped pattern of the body. The presence of double tails does not seem to have affected the lizard's welfare.
The specimen was deposited in the herpetology collection the of Juiz de For a Federal University (CHUFJF 922). We thank the Brazilian environmental agency, IBAMA, for issuing the collection permit (16895-1).

***OPHISAURUS COMPRESSUS* (Island Glass Lizard). SWIMMING.** *Ophisaurus compressus* is a legless anguid native to the southeastern United States (Holman 1971. Cat. Amer. Amph. Rept. 113:1–2). The habitat of this species is described as pinelands (Duellman and Schwartz 1958. Bull. Florida State Mus. 3:181–324) and rosemary-palmetto scrub (Telford 1959. Copeia 1959:100–119), although Neill (1948. Herpetologica 4:153–158) found them under tidal wrack on sandy beaches. As its common name suggests, *O. compressus* is often found on offshore barrier islands, but over-water dispersal by any species of *Ophisaurus* is undocumented.

At 1253 h on 29 March 2012 while kayaking, we encountered an adult *O. compressus* in the Intracoastal Waterway in Flagler Co., Florida, USA (29.621958°N, 81.210497°W, datum WGS 84). This section of the Intracoastal Waterway is within the Guana Tolomato Matanzas National Estuarine Research Reserve (GTMNERR), and contains numerous spoil islands that extend parallel to the waterway for approximately 1.75 km. Upon capture, this *O. compressus* (SVL = 176 mm, tail length = 417 mm) was swimming west towards the nearest spoil island (~ 87 m away) and was approximately 125 m from the mainland.
To our knowledge, this observation provides the first direct evidence for over-water dispersal in *O. compressus*. The frequency of movements among island and mainland habitat at this site is unknown, but this dispersal behavior is likely an important component of the ecology of *O. compressus* despite several potential risks. For example, the saline environment of the estuary (ranges between 11 and 38 ppt depending on the phase of the tide cycle [GTMNERR Water Quality Metadata]) likely poses a physiological challenge to this predominately terrestrial species. In addition, the estuary contains several potential aquatic predators, including Bottlenose Dolphins (*Tursiops truncatus*), American Alligators (*Alligator mississippiensis*), and several predatory fish.

WARNER,** Department of Biology, University of Alabama-Birmingham, Birmingham, Alabama 35294, USA (e-mail: dawarner@uab.edu).

***OPHISOPS ELEGANS* (Snake-Eyed Lizard). BIFURCATION.** *Ophisops elegans* is a diurnal, ground dwelling, medium-sized lacertid lizard. It is widespread in the eastern Mediterranean region from southeastern Europe (northeastern Greece, Bulgaria, including Cyprus) to northeast Sinai and coastal Egypt, eastward to Iraq and Iran. It was also reported from Algeria (Sindaco and Jeremcenko 2008. The Reptiles of the Western Palearctic. Edizioni Belvedere, Latina, Italy. 579 pp.).

On 4 June 2012 at 0905 h, we tried to capture an *O. elegans* male first seen on an oak tree (*Quercus* sp.) in a scrubland area near the field school on Mt. Meron in northern Israel (33.011°N, 35.394°E; 897 m elev.). While trying to capture the individual, its tail was amputated as lacertids are known to readily autotomize their tails (Fitch 2003. J. Herpetol. 37:395–399; Pafilis et al. 2009. Evolution 63:1262–1278). The lizard (TAU 16297) was subsequently captured (50.3 mm SVL; 3.3 g) and its tail collected. The tail, autotomized at the base, was bifurcated approximately 2 cm posterior to the position where it was amputated. One tail tip is 0.5 cm longer than the other. We did not observe other *Ophisops* specimens with bifurcated tails in the field, and few individuals have regenerated tails (less than 1% of all specimens; authors' unpubl. data). We know of no other cases of tail bifurcation in this species (including 360 other Israeli specimens kept at the Tel Aviv University Zoological Museum).

***PHRYNOSOMA CORNUTUM* (Texas Horned Lizard). NECROPHILIA.** Necrophilia has been documented in only five lizard species to our knowledge. These are the Giant Ameiva (*Ameiva ameiva*) by Vitt 2003 (*In* Pianka and Vitt [eds.], Lizards: Windows to the Evolution of Diversity, p. 103. Univ. of California Press, Berkeley) and Costa et al. 2010 (Herpetol. Notes 3:79–83), the Long-nosed Leopard Lizard (*Gambelia wislizenii*) in Fallahpour 2005 (Herpetol. Rev. 36:177–178), the Lesser Earless Lizard (*Holbrookia maculata*) in Brinker and Bucklin 2006 (Herpetol. Rev. 37:466), the Western Fence Lizard (*Sceloporus occidentalis*) in Shedd and Eisenburg 2012 (Herpetol. Rev. 43:338), and the Sleepy Lizard (*Tiliqua rugosa*) in Sharrad et al. 1995 (W. Austr. Nat. 20:33–35) and How and Bull 1998 (Herpetol. Rev. 29:240). Here we report this behavior observed in a sixth lizard species, *Phrynosoma cornutum*. We believe this to be the first recorded observation of necrophilia in this species.

While driving Owen Prather Highway (also known as New Mexico Highway 506) in Otero Co., New Mexico, USA, on 25 May 2012, we encountered two dead *Phrynosoma cornutum* killed by the vehicle in front of us (32.520211°N, 105.980033°W). We stopped to examine the scene and found that one of the lizards was male and the other was female. Based on their slightly overlapping positioning, we presume the lizards were attempting to mate at the time of death. While examining the dead lizards, a living conspecific approached the area, head-bobbing. Although not captured, the enlarged basal region of its tail suggests it was a male. Fearing this lizard would also be killed by vehicle traffic, we attempted scaring it away from the road by walking towards it.

FIG. 1. A living *Phrynosoma cornutum* male positioning itself on top of a freshly run-over female conspecific, next to a simultaneously run-over male conspecific.

PHOTO BY MARCELO AROCA

FIG. 1. Predation of *Podarcis hispanicus* by *Steatoda nobilis* in Villaviciosa de Odón, Spain.

The lizard would flee a short distance (approximately 1 m) when approached, but would return closer to the area of the dead lizards when we would back away a few steps. Having noticed this, we then allowed the male to approach the dead lizards without interfering. The male continued head-bobbing as it approached, placed one of its front limbs on the female's back, and positioned himself on top of the dead female (Fig. 1). It then would position its pelvis to either side of the female's body and would try to slide the lower half of its body under her, attempting to mate. The dead lizards were then moved to prevent the living male, other horned lizards, and scavenging wildlife species from being potentially attracted to the road. The male temporarily left the scene during this activity, but returned to where the dead lizards had been as soon as we moved approximately 1 m away. In an attempt to remove any remaining attractants, a shovel load of soil was then placed over the area where the dead lizards had been, and the male left the area altogether.

Because of the lack of behavioral interactions with the dead conspecifics, we believe this male was operating primarily on olfactory senses. Olfactory cues have been noted in this genus as being important in mating, interactions with conspecifics and other species, and in the marking of sites (Tollestrup 1981. Herpetologica 37:130–141). We believe this observation supports those claims, as the male lizard returned to the site even after the dead lizards were removed from the location of initial interaction. We also believe this observation suggests an intense drive for males of this species to reproduce when in the presence of a reproductively active, receptive female (based on the presumed mating positioning of the dead lizards), even if the potential mate is recently deceased and in the presence of observers who would be recognized as a physical threat and avoided under other circumstances. This observation occurred in a remote area where habituation of the lizard to humans is unlikely.

JEREMY S. LANE, 412 S. Spikes Rd, Corsicana, Texas 75110, USA (e-mail: jeremy_lane@ymail.com); **ERIKA VAN BUREN**, 10936 Cardigan Drive, El Paso, Texas 79936, USA.

***PODARCIS HISPANICUS* (Iberian Wall Lizard). PREDATION.** *Podarcis hispanicus* is a small lizard that inhabits most of the Iberian Peninsula, southern France, and North Africa. Its ability to adapt to varied environments has facilitated its dispersal to areas occupied by humans. This trend is shared by other organisms such as certain arthropods. In many situations the latter may prey on these lizards, while in others, the opposite may occur. It has been previously reported that large roaming spiders are able to sporadically catch reptiles (e.g., Hamilton 2010. Herpetol. Rev. 42:603; Raven 1990. Mem. Queensland Mus. 29:448), nevertheless, the evidence related to small spiders acting as predators is somewhat scarce.

On 10 March 2011 at 1415 h, a *Podarcis hispanicus* was found trapped in a garden at a residence outside Madrid, Spain (40.35699972°N, 3.90099983°W). It was entangled in a web made by a False Widow Spider (*Steatoda nobilis*) (Fig. 1), which repeatedly bit and wrapped the lizard, leaving it motionless. After a few minutes, the lizard was still alive but unable to move, while the spider came out of hiding several times in order to reinforce the structure and bite the prey again.

ROBERTO GARCÍA-ROA, Fonoteca Zoológica, Departamento de Biodiversidad y Biología Evolutiva, Museo Nacional de Ciencias Naturales (CSIC), José Gutiérrez Abascal, 2, 28006, Madrid, Spain (e-mail: roberto.garcia.roa@gmail.com); **MARCELO AROCA**, Juan de la Cierva, 10, 28670, Villaviciosa de Odón, Madrid, Spain (e-mail: marcelo_aroca@hotmail.com); **RUBÉN DE BLAS**, Hacienda de Pavones, 100, 28030 Madrid, Spain.

***SCELOPORUS CLARKII* (Clark's Spiny Lizard). ENDOPARASITES.** *Sceloporus clarkii* occurs from central Arizona and southwestern New Mexico, USA, to northern Jalisco, Mexico (Stebbins 2003. A Field Guide to Western Reptiles and Amphibians, 3rd ed. Houghton Mifflin Co., New York. 533 pp.). To date, the only report of helminths from *S. clarkii* are the cestodes *Mesocestoides* sp. and *Oochoristica scelopori* and the nematodes *Cyrtosomum penneri, Physaloptera retusa, Piratuba prolifica, Skrjabinoptera phrynosoma,* and *Spauligodon giganteus* (Goldberg et al. 1994. J. Helminthol. Soc. Washington 61:73–83). The purpose of this paper is to add to the helminth list of *S. clarkii.*

Two male *S. clarkii* (mean SVL = 83.0 ± 4.2 SD, range = 80–86 mm) collected at Mazatlan (23.2167°N, 106.4167°W), Sinaloa, Mexico and deposited in the herpetology collection of the Natural History Museum of Los Angeles County (LACM), Los Angeles, California, USA as LACM 95628 (collected July 1960) and LACM 95637 (collected August 1963) were examined. The digestive tract was removed through a mid-ventral incision and the esophagus, small and large intestines were examined for helminths using a dissecting microscope. One species of Nematoda

was found which was cleared in a drop of lactophenol, coverslipped on a microscope slide, studied under a compound microscope, and identified as *Strongyluris similis* from the large intestines of LACM 95628 (1 female) and LACM 95637 (3 females). Voucher helminths were deposited in the United States National Parasite Collection, Beltsville, Maryland, USA as *Strongyluris similis* (USNPC 105895). *Strongyluris similis* is a common parasite of sceloporine lizards (Goldberg et al. 1995. J. Helminthol. Soc. Washington 62:188–196; Goldberg et al. 1996. Am. Midl. Nat. 135:299–309; Goldberg et al. 2003. Southwest. Nat. 48:208–217). *Sceloporus clarkii* represents a new host record for *Strongyluris similis*; Sinaloa, Mexico is a new locality record.

We thank Gregory Pauly (LACM) for permission to examine *S. clarkii*.

BURSEY**, Department of Biology, Pennsylvania State University, Shenango Campus, Sharon, Pennsylvania 16146, USA (e-mail: cxb13@psu.edu); **JEANETTE ARREOLA**, Department of Biology, Whittier College, PO Box 634, Whittier, California 90608, USA (e-mail: jarreola@poets.whittier.edu).

***SCELOPORUS CLARKII* (Clark's Spiny Lizard). NOCTURNAL FORAGING ACTIVITY.** On 1 June 2007, an adult male *Sceloporus clarkii* was observed to be active at night during a full moon in tropical dry forest habitat near Alamos, Sonora, Mexico (27.0167°N, 108.9333°W; elev. 396 m). We found *S. clarkii* foraging for insects with poor success at 2230 h; only one attempt to feed on moths was successful. This behavior was observed at a distance of 4 m from the lizard for a period of two hours. Following our observations, the lizard slowly took shelter within a rock crevice located 1.5 m from the foraging locality. Unfortunately, we could not take its body temperature (T_b), but temperatures recorded at the nearest meteorological station were 35.5°C at 2230 h and 33°C at 0030 h (T_{ave} = 31.2°C, T_{max} = 43°C, T_{min} = 19.8°C).

Diurnal reptiles are characterized by maintaining a high T_b to perform daily activities (Avery 1982. *In* C. Gans and F. H. Pough [eds], Biology of the Reptilia, Vol. 12, Physiology C, pp. 93–166. New York). Nocturnal activity in diurnal lizard species has only been reported in laboratory conditions (Dial 1978. Science 155:1551–1553). However, the finding of diurnal species on roads at night has been documented previously (Trombulak and Frissell 1999. Conserv. Biol. 14:18–30). Many authorities suggest that diurnal reptiles are attracted to roads at night to elevate their body temperatures during cooler periods, thus turning the roads into "heat islands" (Dodd et al. 1989. J. Herpetol. 23:197–200.). Nevertheless, more data are necessary to qualify these observations as true activity, because species are not thermally passive during inactivity and select stable thermal microenvironments (Ruben 1976. Herpetologica 32:323–325) and a high nocturnal body temperature may promote digestion (Harlow et al. 1976. J. Comp. Physiol. 111:1–6).

More often, suboptimal ambient temperatures at night preclude the activity of many species of reptiles. It is at this time when T_b falls near or below the level of the minimum voluntary temperature, which is the lower limit for activity. It is well-known that many reptiles take shelter before the natural environment becomes thermally unfavorable. However, in the case of *S. clarkii,* high diurnal temperatures (up to 43°C) resulting in elevated temperatures of the air, tree trunks and rocks, was enough to maintain T_b in the activity range until midnight.

It can be difficult to establish the limits between activity and inactivity, as some species are known to opportunistically engage prey under suboptimal environmental conditions. Thus, the environment may maintain T_b adequate for low levels of activity. According to Huey (1982. *In* C. Gans and F. H. Pough [eds], *op. cit.*, pp. 25–91) some reptile species voluntarily spend the night outside of their burrows to prolong potential foraging time and actively select relatively low body temperatures (i.e., voluntary hypothermia). Furthermore, voluntary nocturnal hypothermia produces a lower T_b that reduces metabolic loss throughout the night. This may be an adaptive response for individuals that fail to obtain food during the day, even if voluntary hypothermia becomes unfavorable and makes the lizard more vulnerable to nocturnal predators. In the case of *S. clarkii*, this hypothesis may explain the fact that we found the lizard outside its burrow. We also suggest that the full moon light helps to prolong foraging time at night, as long as the degree of voluntary hypothermia does not fall below the level of the minimum voluntary temperature.

The physiological and ecological advantages of voluntary hypothermia may be important for species affected by global warming, as the behavior could serve as a mechanistic response to minimize the risk of overheating stress during diurnal foraging. For example, the lizard *Sceloporus serrifer* in the Yucatan Peninsula has been observed to have fewer opportunities for foraging during the day because the species limits its period of activity due to the extremely high diurnal temperatures recorded throughout the year (Sinervo et al. 2010. Science 328:894–899). Additional nocturnal surveys are needed in order to document nighttime active foraging behavior or voluntary hypothermia, particularly in populations and species where the probabilities of extinction are high due to climate change (Sinervo et al. 2010, *op. cit.*). This would help to determine the frequency of this phenomenon and whether it is more common in species more sensitive to global changes in climatic conditions.

NORBERTO MARTÍNEZ-MÉNDEZ, Laboratorio de Ictiología, Departamento de Zoología, Escuela Nacional de Ciencias Biológicas del Instituto Politécnico Nacional (e-mail: nmm@ibiologia.unam.mx); **RAFAEL A. LARA-RESENDIZ**, Posgrado en Ciencias Biológicas, Instituto de Biología, Universidad Nacional Autónoma de México, AP 70515, CP 04510, Distrito Federal, México (e-mail: rlara@ibiologia.unam.mx); **CHRISTOPHER BLAIR**, Department of Biology, Duke University, Box 90338, Durham, North Carolina 27708, USA (e-mail: Christopher.Blair@duke.edu).

***SCELOPORUS MAGISTER* (Desert Spiny Lizard). ENDOPARASITES.** *Sceloporus magister* occurs in the Sonoran Desert of Arizona, southern California, Sonora, northern Baja California, and the Colorado Plateau in southeastern Utah, adjacent Arizona, and Colorado and northwestern New Mexico (Jones and Schwalbe 2009. *In* Jones and Lovich [eds.], Lizards of the American Southwest: A Photographic Field Guide, pp. 226–229. Rio Nuevo Publishers, Tucson, Arizona). The previous reports of helminths from *S. magister* (*sensu stricto*) are listed in Goldberg et al. (1994. J. Helminthol. Soc. Washington 61:73–83). The purpose of this note is to add to the helminth list of *S. magister*.

Two female *S. magister* (mean SVL = 96.5 mm ± 5.0 SD, range, 93–100 mm) collected June 1966 at Guaymas (27.316667°N, 109.916667°W) Sonora, Mexico, and deposited in the herpetology collection of the Natural History Museum of Los Angeles County (LACM), Los Angeles, California, USA as LACM 25098, 25099 were examined. The digestive tract was removed through a mid-ventral incision and the esophagus, stomach, and small and large intestines were examined for helminths under a dissecting microscope. Individuals of one species of Nematoda were found in the large intestines; these were cleared in a drop of

lactophenol, cover-slipped on a microscope slide, studied under a compound microscope, and identified as 480 *Cyrtosomum scelopori* in LACM 25098 and 649 in LACM 25099. Voucher helminths were deposited in the United States National Parasite Collection, Beltsville, Maryland, USA as *Cyrtosomum scelopori* (USNPC 105897). Other hosts for *C. scelopori* are listed in Baker (1987. Mem. Univ. Newfoundland, Occas. Pap. Biol. 11:1–325), Moravec et al. (1997. J. Helminthol. Soc. Washington 64:240–247), and Mayén-Peña and Salgado-Maldonado (1998. J. Helminthol. Soc. Washington 65:108–111).

Cyrtosomum scelopori is an oxyurid nematode that does not utilize an intermediate host (Anderson 2000. Nematode Parasites of Vertebrates: Their Development and Transmission. CABI Publishing, Oxon, U.K. 650 pp.). Infection likely occurs by *S. magister* licking soil containing *C. scelopori* eggs. *Sceloporus magister* is a new record for *Cyrtosomum scelopori*. Sonora, Mexico is a new locality record.

We thank Gregory Pauly (LACM) for permission to examine *S. magister*.

STEPHEN R. GOLDBERG, Department of Biology, Whittier College, PO Box 634, Whittier, California 90608, USA (e-mail: sgoldberg@whittier.edu); **CHARLES R. BURSEY**, Department of Biology, Pennsylvania State University, Shenango Campus, Sharon, Pennsylvania 16146, USA (e-mail: cb13@psu.edu); **JEANETTE ARREOLA**, Department of Biology, Whittier College, PO Box 634, Whittier, California 90608, USA (e-mail: jarreola@poets.whittier.edu).

***SCELOPORUS ORCUTTI* (Granite Spiny Lizard). ENDOPARASITES.** *Sceloporus orcutti* occurs from lower slopes of the Peninsular Ranges of southern California, southward to just north of the Cape Region of Baja California and is largely restricted to granite boulders (Stebbins 2003. A Field Guide to Western Reptiles and Amphibians, 3rd ed. Houghton Mifflin Co., New York. 533 pp.). To date, the only report of helminths from *S. orcutti* is that of the cestode *Oochoristica scelopori* and the nematode *Spauligodon giganticus* (Goldberg and Bursey 1991. J. Wildl. Dis. 27:355–357). The purpose of this paper is to add to the helminth list of *S. orcutti*.

Two male *S. orcutti* (mean SVL = 87.0 ± 5.7 SD, range = 83–91 mm) were collected in April 1978 from Cataviña (29.73194°N, 114.72083°W), Baja California, Mexico, and deposited in the herpetology collection of the Natural History Museum of Los Angeles County (LACM), Los Angeles, California, USA, as LACM 128066, 128067. The digestive tract was removed through a midventral incision and the esophagus, stomach, and small and large intestines were examined for helminths under a dissecting microscope. Individuals of three species of Nematoda were found; these were cleared in a drop of lactophenol, cover-slipped on a microscope slide, studied under a compound microscope, and identified as *Parapharyngodon californiensis* (2 females) and *Strongyluris similis* (7: 3 males, 4 females) from the large intestine of LACM 128066 and *Thubuanea iguanae* (1 male) from the small intestine of LACM 128067. Voucher helminths were deposited in the United States National Parasite Collection, Beltsville, Maryland, USA as *Parapharyngodon californiensis* (USNPC 105898), *Strongyluris similus* (USNPC 105899), and *Thubunaea iguanae* (USNPC 105900).

Parapharyngodon californiensis has been previously known only from the xantusiid lizards *Xantusia bolsonae, X. henshawi*, and *X. vigilis* (Goldberg et al. 1993. J. Helminthol. Soc. Washington 60:165–169). *Sceloporus orcutti* is the fourth lizard species and first member of the Phrynosomatidae reported to harbor *P. californiensis*. *Parapharyngodon californiensis* is an oxyurid nematode that does not utilize an intermediate host (Anderson 2000. Nematode Parasites of Vertebrates: Their Development and Transmission. CABI Publishing, Oxon, U.K. 650 pp.). Infection likely occurs by *S. orcutti* licking substrate containing *P. californiensis* eggs. *Strongyluris similis* is a common parasite of sceloporine lizards (Goldberg et al. 1995. J. Helminthol. Soc. Washington 62:188–196; Goldberg et al. 1996. Am. Midl. Nat. 135:299–309; Goldberg et al. 2003. Southwest. Nat. 48:208–217). *Thubunaea iguanae* is known from a large number of lizards from the southwestern United States (McAllister et al. 2008. Comp. Parasitol. 75:241–254). Both *S. similis* and *T. iquanae* utilize insect intermediate hosts. *Parapharyngodon californiensis, Strongyluris similes,* and *Thubunaea iguanae* represent new host records for *S. orcutti*. Baja California, Mexico is a new locality record for *P. californiensis*.

We thank Gregory Pauly (LACM) for permission to examine *S. orcutti*.

STEPHEN R. GOLDBERG, Department of Biology, Whittier College, PO Box 634, Whittier, California 90608, USA (e-mail: sgoldberg@whittier.edu); **CHARLES R. BURSEY**, Department of Biology, Pennsylvania State University, Shenango Campus, Sharon, Pennsylvania 16146, USA (e-mail: cxb13@psu.edu); **JEANETTE ARRELOA**, Department of Biology, Whittier College, PO Box 634, Whittier, California 90608, USA (e-mail: jarreola@poets.whittier.edu).

***TRAPELUS MUTABILIS* (Desert Agama). REPRODUCTION.** *Trapelus mutabilis* is known from Egypt, Sinai, Syria, and Israel (Uetz [ed.], The Reptile Database, http://www. reptile-database. org. accessed 15 October 2012). It is diurnal, living at the base of dunes with dense vegetation (Schleich et al. 1996. Amphibians and Reptiles of North Africa, Koenigstein, Germany. 630 pp.). Information on *T. mutabilis* reproduction is limited and consists of one clutch of 5–7 eggs deposited in June, sperm production in spring with mating in April–May (Schleich et al., *op. cit.*). The purpose of this note is to provide additional information on *T. mutabilis* reproduction from a histological examination of gonads from museum specimens.

A sample of *T. mutabilis* deposited in the Zoological Museum of the Department of Zoology, Tel-Aviv University (TAUM), Tel Aviv, Israel was examined. The sample consisted of 18 males (mean SVL = 62.0 mm ± 4.5 SD, range = 56–73 mm), 9 females (mean SVL = 65.8 mm ± 6.9 SD, range = 56–77 mm) and one juvenile female (SVL = 50 mm) collected 1944–1986 in Israel (31.5°N, 34.75°E). Vouchers used in this study include: TAUM: 674, 1095, 1319, 1459, 1761, 1765, 2540, 3004, 3067, 3305, 3355, 3356, 3673, 4068, 4867, 5376, 5777, 6002, 6419, 6683, 7108, 7119, 7120, 8480, 13184, 13185, 13563, 13945.

A cut was made in the lower abdominal cavity and the left testis or ovary was removed, embedded in paraffin, cut at 5 µm sections and stained with Harris hematoxylin followed by eosin counterstain. Oviductal eggs were counted. Histology slides are deposited in TAUM.

Two stages were noted in the ovarian cycle: 1) quiescent, no yolk deposition; 2) early yolk deposition, basophilic vitellogenic granules in ooplasm. All females from the following months exhibited quiescent ovaries, sample size in parentheses: March (N = 1); April (N = 2); May (N = 1); August (N = 1); September (N = 1); October (N = 1); November (N = 1). A second female collected in May (TAUM 1095, SVL = 64 mm) contained 5 oviductal eggs and concurrent early yolk deposition for a subsequent clutch. This is the first evidence that *T. mutabilis* may produce multiple

TABLE 1. Monthly stages in the testicular cycle of 18 *Trapelus mutabilis* from Israel.

Month	N	Regression	Spermiogenesis
March	4	0	4
April	7	0	7
May	2	0	2
June	2	1	1
August	2	2	0
October	1	1	0

clutches in the same reproductive season. One female (SVL = 50 mm) with quiescent ovaries was considered a sub-adult.

Two stages were observed in the testicular cycle: 1) Regression, the germinal epithelium in the seminiferous tubules is reduced to 1-3 layers of predominantly spermatogonia and Sertoli cells; 2) spermiogenesis, lumina of the seminiferous tubules are lined by sperm or rows of metamorphosing spermatids. The presence (Table 1) of males with regressed testes from June and August, marking the end of spermiogenesis, and a female with oviductal eggs in May indicates that *T. mutabilis* follows a seasonal reproductive cycle with breeding and ovulation in spring, typical of temperate zone lizards (Fitch 1970. Univ. Kansas Mus. Nat. Hist. Misc. Publ. 52:1–247).

I thank Shai Meiri (TAUM) for permission to examine *T. mutabilis*, Ezra Maza for facilitating the loan and the National Collections of Natural History at Tel Aviv University for providing samples of *T. mutabilis* for this study.

STEPHEN R. GOLDBERG, Whittier College, Department of Biology, P.O. Box 634, Whittier, California 90608, USA; e-mail: sgoldberg@whittier.edu.

VARANUS MERTENSI **(Mertens' Water Monitor). PREDATION.** Identifying trophic links is necessary to construct food webs, which in turn are critical for understanding multiple areas of the ecology of a given species, including community interactions, predator-prey dynamics, and the impacts of invasive species. Trophic links are often poorly understood in the tropics, including the Australian wet-dry tropics.

Varanus mertensi is a large aquatic lizard (up to about 1 m in total length) inhabiting freshwater systems in tropical Australia (Cogger 2000. Reptiles and Amphibians of Australia. Reed New Holland, Sydney. 808 pp.). Although few predators are large enough to prey upon adult *V. mertensi*, eagles are an exception. We report a case of *V. mertensi* predation by a White-bellied Sea Eagle (*Haliaeetus leucogaster*) in tropical Australia, based on remains under a feeding perch near an eagle nest. We discuss the importance of monitor lizards as prey for eagles, and implications for population declines in monitors with the arrival of invasive Cane Toads (*Rhinella marina*) in northern areas of Western Australia.

On 16 May 2012 the desiccated tail of a *V. mertensi* was found under a *Eucalyptus* tree, approximately 90 m from an active sea eagle nest at the junction of the Chamberlain and Pentecost rivers at El Questro Wilderness Park in the Kimberley Region (15.968847°S, 127.928739°E). The tail was on the ground next to multiple bones of two individual catfish, and several feathers of a Sulphur-crested White Cockatoo (*Cacatua galerita*). The tree was one of several feeding perches of a pair of sea eagles. An earlier climb into the eagle nest on 9 May 2012 confirmed two incubating eggs. The nest was ca. 30 m high in a *Eucalyptus* tree. The sex of the dead lizard could not be determined, but based on size was a medium-sized adult. Although it is possible that the eagle found the lizard as carrion, the prey item was well within the prey-size range of the raptor.

Sea eagles are previously unreported predators of *V. mertensi*, but this probably reflects the dearth of dietary studies of tropical Australian eagles, rather than an infrequent trophic interaction. Sea eagles are limited to coastal areas and large inland rivers. In the latter areas, where *V. mertensi* is widespread, the monitor is possibly an important food item for the eagles. *Varanus mertensi* is one of three species of Australian monitor lizards that suffer severe population-level declines, via lethal toxic ingestion, with the invasion of *Rhinella marina* (e.g., 87–93%, Doody et al. 2009. Anim. Conserv. 12:46–53). Cane Toads began to invade the site in 2012 (S. Doody, unpubl. data). Thus, invading Cane Toads may be essentially removing an important prey item for the eagles, potentially influencing the energetics and reproductive success of these apex predators. Regardless, we predict a shift in the diet in sea eagles as a result of toad invasion and declines in *V. mertensi* (and of *V. panoptes*; Doody and Cherriman 2012. Herpetol. Rev. 43:653–654). Dietary surveys of eagle nest remains before and after toad invasion in the Kimberley Region would test this prediction.

J. SEAN DOODY, Department of Ecology and Evolutionary Biology, The University of Tennessee, Knoxville, Tennessee, 37916, USA (e-mail: jseandoody@gmail.com); **SIMON CHERRIMAN**, 180 Glendower St., Parkerville, 6081, Western Australia (e-mail: aquila84@iinet.net.au).

SQUAMATA — SNAKES

AGKISTRODON CONTORTRIX **(Copperhead). DIET AND ACCIDENTAL MORTALITY.** At ca. 1115 h on 08 June 2012, an adult male *Agkistrodon contortrix* (total length = 824 mm, SVL = 705 mm) was found near death in a rural yard, ca. 9.8 km WSW Brogdon, Sumter Co., South Carolina, USA (33.77818°N, 80.35468°W, datum: WGS84). Both mandibles of a bird's bill were protruding outward from separate exit wounds on the left side of the snake's body, ca. 90 mm posterior to the tip of its snout (Fig. 1), and a small point of broken mandibular bone was protruding outward on the right side. The snake was found dead a few hours later. The partial skull of a *Corvus ossifragus* (Fish Crow) was later removed from the snake's throat. No additional remains were in the digestive tract and the entire bird would have been far too large for the snake to swallow. The angle of the bill protrusion indicated that the head was most likely swallowed backward. This, along with the fragmented condition of the skull, suggests that the snake had encountered only the detached partial head of the bird and attempted to scavenge it.

Numerous reports exist of injury and mortality in snakes during feeding attempts. These include accounts of indigestible foreign objects that may contain the scent of prey (Palmer and Braswell 1995. Reptiles of North Carolina. Univ. North Carolina Press, Chapel Hill. xiii + 412 pp.), as well as trauma from natural prey items with sharp spines or otherwise injurious body parts (Carr 1940. A Contribution to the Herpetology of Florida. University of Florida, Gainesville. 118 pp.). As a generalist feeder and known scavenger, *A. contortrix* may fall victim to such accidental mortality relatively frequently. To our knowledge, this represents the first record of *A. contortrix* feeding on *C. ossifragus*, or attempting to feed on any portion of such a large bird.

The snake and partial crow skull are deposited in the collections of the North Carolina State Museum of Natural Sciences

FIG. 1. *Agkistrodon contortrix* with attempted meal (head of a *Corvus ossifragus*, Fish Crow) that proved fatal.

(NCSM 79738). Brian J. O'Shea helped confirm identification of the skull.

***AMPHIESMA STOLATUM* (Striped Keelback). PREDATION.** *Amphiesma stolatum* is a small (to 80 cm total length) diurnal snake found throughout South and Southeast Asia. It is one of the most common snakes in this region, found in villages, paddy fields, thick grass, bushes, and gardens (Whitaker and Captain 2004. The Snakes of India. Draco Books, India. 481 pp.). Herein, we report predation by a free ranging chicken on an adult *A. stolatum* from a village adjacent to Lawachara National Park, Bangladesh (25.8907694°N, 088.8502083°E; datum WGS 84). On 15 April 2012, at ca. 1100 h, while conducting a visual herpetological survey in the village, we observed an adult domestic chicken in a backyard garden preying upon an adult *A. stolaum* (Fig. 1). It is likely that many other birds prey upon *A. stolatum* as well.

FIG. 1. Predation by a free ranging chicken on an adult *Amphiesma stolatum*.

We thank The Orianne Society and Center for Advanced Research and Natural Management, for funding and logistical support. The field work was conducted under the forest department permit given to S.M.A. Rashid (permit: 2M-47/11).

***ATRACTUS GUENTHERI* (Günther's Ground Snake). REPRODUCTION.** *Atractus guentheri* has a very restricted distribution in the coastal Atlantic Rainforest in the southeast of the state of Bahia, Brazil (Fernandes and Argôlo 1995. Bol. Mus. Nacional, Nova Série, Zoologia 397:1–5; Passos et al. 2010. Zootaxa 2364:1–63). Many aspects of its natural history are poorly known with nothing reported about reproduction (Fernandes and Puorto 1993. Mem. Inst. Butantan, 55:7–14). Here we provide the first data on clutch size, egg morphometry, and timing of oviposition for *A. guentheri*.

At 1830 h on 07 December 2011, during the rainy season in the Atlantic rainforest of Brazil, an adult female *A. guentheri* (SVL = 427 mm, tail length = 43 mm) was captured by local farmers crossing a dirt road 15 m from a large river (Rio de Contas) near the city of Itabuna, Bahia, Brazil (14.7976°S, 39.2334°W, datum WGS84; elev. 38 m). The road passed through vegetation locally known as Cabruca, a Cacao plantation system that retains the largest trees. Two days post capture, the female deposited six white elliptical eggs. Mean egg measurements were: length = 30.2 mm (range = 27.8–32.7 mm); width = 11.3 mm (range = 10.8–11.8 mm); mass = 2.67 g (range = 2.4–2.9 g). Unfortunately, all eggs were lost during incubation and their fertility could not be assessed. The *A. guentheri* was deposited at the Reptile Collection of Museu de Zoologia da Universidade Federal da Bahia (MZUFBA–2382).

Breno Hamdan and Daniela Coelho provided helpful suggestions on the manuscript.

THIAGO FILADELFO, Programa de Pós-Graduação em Ecologia da Universidade de Brasília, Campus Darcy Ribeiro, Asa Norte, CEP: 70910-900, Brasília, Distrito Federal, Brazil (e-mail: thiago_bioufba@yahoo.com.br); **MILENA CAMARDELLI**, Programa de Pós-Graduação em Ecologia e Biomonitoramento da Universidade Federal da Bahia, Campus de Ondina, CEP: 40170-110, Salvador, Bahia, Brazil (e-mail: milenacamardelli@yahoo.com.br); **RAFAEL OLIVEIRA DE ABREU**, Programa de Pós-Graduação em Diversidade Animal da Universidade Federal da Bahia, Campus de Ondina, CEP: 40170-110, Salvador, Bahia, Brazil (e-mail: rafaoabreu@gmail.com).

***BOA CONSTRICTOR* (Boa Constrictor). REPRODUCTION / FACULTATIVE PARTHENOGENESIS.** Facultative parthenogenesis is the alternation between sexual and asexual reproduction (Booth et al. 2011. J. Hered. 102:759–763). In vertebrates, facultative parthenogenesis has mostly been recorded in captive animals, but recently documented in wild populations (e.g., snakes; Booth et al. 2012. Biol. Lett. *in press*). This mode of parthenogenesis is rare in reptiles (Lampert 2008. Sex Dev. 2:290–301). In lizards, it has only been reported in *Phymaturus patagonicus* (Chiszar et al. 1999. Herpetol. Rev. 30:98), monitor lizards (Lenk et al. 2005. Amphibia-Reptilia 26:507–514), and Komodo Dragons (Watts et al. 2006. Nature 444:1021–1022). In snakes, facultative parthenogenesis has been reported pitvipers, *Agkistrodon contortrix* and *A. piscivorus* (Schuett et al. 1998. Herpetol. Nat. Hist. 5:1–10; Booth and Schuett 2011. Biol. J. Linn. Soc. 934–942; Booth et al. 2012, *op. cit.*), and in the boid *Epicrates maurus* (Booth et al. 2011. J. Hered. 102:759–763). Recently, Booth et al. (2011, *op.*

cit.) recorded the first evidence of facultative parthenogenesis in *Boa constrictor*. Here we report the second record of facultative parthenogenesis in captivity for *B. constrictor*.

A female *B. constrictor*, born in captivity (July 2003), was maintained in complete isolation in a glass enclosure with lighting and constant temperature between 28 and 32°C and was fed weekly. On 27 May 2012, RALR and BCLB recorded that the snake (SVL = 1700 mm, 3340 g) gave birth to 20 dead all male hatchlings and ten infertile ova. The average measurements of the offspring were: SVL = 259 ± 1.13 mm (range = 208–312 mm); tail length = 39 ± 0.15 mm (range = 32–45 mm); 18.5 ± 1 g (range = 14.3–23.9 g). No malformations were present. We cannot distinguish the reason for the death of hatchlings, but one month before parturition metronidazole medication was administered as an antibiotic. The dead hatchlings and the ova are deposited in the Colección Nacional de Anfibios y Reptiles, Instituto de Biología, Universidad Nacional Autónoma de México.

We thank the Lara-Resendiz family for care of the boa and Christopher Blair for helpful comments that improved the manuscript.

***CONOPHIS VITTATUS* (Striped Road Guarder). DEFENSIVE BEHAVIOR / DEATH FEIGNING.** Thanatosis or death feigning behavior has been reported in several species of snakes (Gehlbach 1970. Herpetologica 26:24–34; Zeeshan et. al. 2011. Herpetol. Notes 4:295–267). On 14 February 2012, at 1930 h, I found an adult *C. vittatus* (SVL = 330 mm) under a log in the ecotone between tropical deciduous forest and oak forest in the Municipality of Villa Purificación, Jalisco, Mexico (19.782505°N, 104.719172°W, datum WGS84; elev. 585 m). Immediately upon capture the snake displayed typical defensive behavior: agitation, coiled posture, fast movements, musk production, and biting attempts. The snake was placed in a bag for further photography. When released, it rotated the anterior third of its body onto its back with its mouth wide open and tongue sticking out (Fig. 1) and did not demonstrate any reaction to manipulation. After approximately 1 min, the snake rotated the full length of its body and remained immobile on its back. I was able to handle the specimen for about 11 min. before the snake began to react and attempt to escape. Photographs of the snake were deposited at University of Texas Arlington Digital Collection (UTADC 7499, 7500, 7574).

FIG. 1. Death-feigning behavior in *Conophis vittatus* from Jalisco, Mexico.

I thank Simón Guerrero Cruz and José Carlos Arenas for comments on the manuscript and Mario A. Iñiguez for field work.

IVÁN T. AHUMADA-CARRILLO (e-mail: lepidus320@hotmail.com), Centro Universitario de Ciencias Biológicas y Agropecuarias, Universidad de Guadalajara, Carretera a Nogales Km. 15.5, Las Agujas, Nextipac, Zapopan, Jalisco, México.

***CONTIA TENUIS* (Common Sharp-tailed Snake). ALBINISM.** Despite high population densities throughout the northern California portion of its range, little is known about *Contia tenuis* (Hoyer et al. 2006. Northwest. Nat. 87:195–202) and aberrant phenotypes in this species are rarely observed (R. Hoyer, pers. comm.). Here I report on albinism in *C. tenuis*.

At 1350 h on 11 February 2012, I found an aberrant *Contia tenuis* in Bidwell Park, Chico, Butte Co., California, USA (39.7458°N, 121.8086°W; datum: WGS84). The specimen was a juvenile, approximately 118 mm (total length), lacking normal pigmentation in the skin and eyes, suggesting albinism (Fig. 1A). The snake was found thermoregulating under a piece of plywood lying beneath a large Valley Oak (*Quercus lobata*). According to Bechtel (1995. Reptile and Amphibian Variants: Colors, Patterns, and Scales. Krieger Publ. Co., Melbourne, Florida. 206 pp.), "true albinism in snakes is a congenital decrease or absence of melanin in the skin, mucosa, and eyes." This description seems appropriate, considering the pink eyes and pale, pinkish orange dorsum of this specimen. Further, the venter was light colored, rather than the typical alternating, dark-light pattern of the belly scutes in normal individuals of this species (Fig. 1B).

FIG. 1. A) Albino *Contia tenuis* from Butte Co., California. B) Venter showing lack of melanin in belly scutes.

COLOR REPRODUCTION SUPPORTED BY THE THOMAS BEAUVAIS FUND

I thank Chris R. Feldman and Richard F. Hoyer for their feedback and encouragement to write up this observation. I also thank Harry W. Greene for reviewing this note and Robert W. Hansen for the reference to literature on the subject of genetic aberrancies in herpetofauna.

JACKSON D. SHEDD, The Nature Conservancy, 11010 Foothill Blvd, Los Molinos, California 96055, USA; e-mail: jackson.shedd@gmail.com.

***CROTALUS ATROX* (Western Diamond-backed Rattlesnake). HABITAT USE.** *Crotalus atrox* is usually found in dry washes, rocky slopes, and open desert (Brennan and Holycross 2006. A Field Guide to Amphibians and Reptiles in Arizona. Arizona Game and Fish Dept., Phoenix, Arizona. 150 pp.; Stebbins 2003. A Field Guide to Western Reptiles and Amphibians. Houghton Mifflin Co., Boston, Massachusetts. 533 pp.). Here, I report encounters with *C. atrox* in an unusual habitat: the leaf litter of Mesquite trees (*Prosopis* sp.). Mesquite usually occurs in a grassland/savannah-like habitat where the trees are not touching, hence tree cover may be 20–50%. In Arizona, near water courses, mesquite forms impenetrable thickets where branches of the trees interlace. On 16 April 2011, between 0930 and 1000 h (air temp = 24°C) on the Tarr Ranch, at the junction of Burro Creek and the Big Sandy River (34.53°N, 113.56°E, datum WGS84; elev. 500 m) in southern Mohave Co., Arizona, USA, I was searching for metal objects under a big thicket of mesquite trees. Lifting up a metal object that was buried 25 cm deep at the base of a mesquite tree, I encountered a large *C. atrox* that was buried so deep that I could not see it until I removed the metal object. About 15 min later, at the edge of another thicket, I was removing some metal wire and surprised two large *C. atrox* that were buried under the wire and leaf litter, which was about 30 cm deep. One was coiled, the other stretched out but touching the other. Mesquite thickets harbor a variety of nesting songbirds, several species of rodents, and lizards, all common prey items of *C. atrox* (Stebbins 2003, *op. cit.*). Thus these thickets may provide a source of food for these reptiles and in the winter and summer heat, the deep leaf litter may provide thermal insulation for inactive snakes.

I want to thank Seth Tarr for access to his property and Erika Nowak for her suggestions.

BAYARD H. BRATTSTROM, Horned Lizard Ranch, P.O. Box 166, Wikieup, Arizona, 85360, USA (e-mail: bayard@hughes.net).

***EIRENIS ROTHII* (Roth's Dwarf Racer). REPRODUCTION.** *Eirenis rothii* is known from Turkey, Syria, Lebanon, and Israel (Baran and Atatür 1998. Turkish Herpetofauna [Amphibians and Reptiles]. Ministry of Environment, Republic of Turkey, Ankara. 214 pp.). The purpose of this note is to provide the first information on the timing of the *E. rothii* testicular cycle.

A sample of 14 *E. rothii* males (mean SVL = 190.3 mm ± 32.0 SD, range = 125–163 mm) collected 1960–1980 in Israel and deposited in the Zoological Museum of the Department of Zoology, Tel-Aviv University (TAUM), Tel Aviv, Israel was examined: TAUM 4009, 5589, 6019, 6020, 7681, 7865, 7870, 7871, 8331, 8491, 10313, 10314, 11146, 12239. A cut was made in the lower abdominal cavity and the left testis and part of the vas deferens was removed, embedded in paraffin, cut into 5 µm sections and stained with Harris hematoxylin followed by eosin counterstain. Histology slides are deposited in TAUM. Three stages in the testicular cycle were noted: 1) Residual spermiogenesis, a few sperm are present in the lumina of the seminiferous tubules from a previous spermiogenesis, germinal epithelium reduced to a few layers of spermatogonia with interspersed Sertoli cells; 2) Regressed, germinal epithelium in seminiferous tubules reduced to a few layers of spermatogonia with interspersed Sertoli cells; 3) Early recrudescence, proliferation of germ cells for the next period of sperm formation (spermiogenesis) has commenced. A few primary spermatocytes are present. Monthly distribution of stages in the testicular cycle with sample size in parenthesis were: January (1) one recrudescence; February (1) one recrudescence; April (7) six regressed, one vas deferens only; May (5) one residual spermiogenesis, one regressed, three recrudescence. Eight of nine examined vasa deferentia (89%) contained sperm. The smallest reproductively active male, sperm in vas deferens (TAUM 8491) measured 175 mm SVL.

The absence of full spermiogenesis or late recrudescence characterized by the presence of secondary spermatocytes and spermatids, and vasa deferentia with sperm in spring, suggests *E. rothii* may follow an aestival spermatogenesis (*sensu* Saint Girons 1982. Herpetologica 328:5–16) in which spermiogenesis is completed in autumn and matings and ovulation occurring in spring. Other congeners of *Eirenis* deposit eggs in summer (Arakelyan et al. 2011. Herpetofauna of Armenia and Nagorno-Karabakh. Society for the Study of Amphibians and Reptiles, Ithaca, New York. 149 pp.), also suggesting they may follow an aestival spermatogenesis.

I thank Shai Meiri (TAUM) for permission to examine *E. rothii*, Erez Maza (TAUM) for facilitating the loan and the National Collections of Natural History at Tel Aviv University for providing samples of *E. rothii* for this study.

STEPHEN R. GOLDBERG, Whittier College, Department of Biology, PO Box 634, Whittier, California 90608, USA; e-mail: sgoldberg@whittier.edu.

***EPICRATES ANGULIFER* (Cuban Boa). DIET.** *Epicrates angulifer* is a medium-sized snake endemic to Cuba, where it is widespread (Schwartz and Henderson 1991. Amphibians and Reptiles of the West Indies. Descriptions, Distributions, and Natural History. Univ. Florida Press, Gainesville. 720 pp.). It inhabits a wide range of habitats, from xerophytic scrub to broadleaf forests, where it is often found in trees up to 10 m in height (Henderson and Powell 2009. Natural History of West Indian Reptiles and Amphibians. Univ. Press Florida, Gainesville. 496 pp.). This species preys on small vertebrates, principally birds and mammals, although frogs, lizards, and other snakes are also taken (Schwartz and Henderson, *op. cit.*; Henderson and Powell, *op. cit.*). Wild individuals are known to hunt domestic fowl (Barbour and Ramsden 1919. Mem. Mus. Comp. Zool. 47:71–213), while captive specimens take a variety of bird species (Morell et al. 1998. Flora y Fauna 2:40–42).

On 24 May 2010, at 0535 h, we found an adult *E. angulifer* (ca. 2000 mm total length) preying on a nestling *Tyrannus dominicensis* (Gray Kingbird) in the gardens surrounding the facilities of the Siboney Biological Station, Siboney-Juticí Ecological Reserve, eastern Cuba (19.9608°N, 75.7155°W; datum NAD 27). The kingbird nest was 7.8 m above ground in a Yarúa Tree (*Caesalpinia violacea*). The snake's tail was coiled around a branch just below the nest and the rest of its body was hanging down, with the anterior portion of the nestling bird's body in the snake's mouth (Fig. 1). The adult kingbird pair defended its nest by flying around the snake, bill-snapping and emitting high-pitched calls, but the snake appeared to be unaffected. At 0605 h the boa finished swallowing its prey and moved to the nest, coiling itself above it. Another young kingbird was found some minutes later, alive on the ground near the nest; we assume it was a sibling of the depredated bird and escaped by dropping from the tree.

FIG. 1. Adult *Epicrates angulifer* swallowing a nestling *Tyrannus dominicensis* (Gray Kingbird) in the Siboney Biological Station, Cuba (the arrow indicates the snake's eye). The nest, wrapped in *Tillandsia* sp. leaves, is situated in the upper area of the photo.

Our observation is the first record of *E. angulifer* preying on *T. dominicensis*. Several authors have mentioned birds in the diet of *E. angulifer* (Henderson and Powell, *op. cit.*) and Vogel (1965. Aquarien Terrarien 12:340–343) reported that the species regularly depredates bird nests, but our observation represents the first documentation of this behavior.

We thank Idea Wild for donating some field equipment, Roimey Vinet García (Siboney Biological Station, BIOECO) for taking the pictures, Chris Rimmer (Vermont Center for Ecostudies, USA) for useful comments on this note, and the Centro Oriental de Ecosistemas y Biodiversidad (BIOECO) for providing permits and facilities.

***ERYTHROLAMPRUS AESCULAPII* (False Coral). DIET.** *Erythrolamprus aesculapii* is a diurnal terrestrial snake that is widely distributed in Brazil (Marques 1996. Rev. Brasil. Biol. 13:747–753). It is strongly ophiophagous, but juveniles also prey on lizards and amphibians. (França et al 2008. Copeia 2008:23–28; Marques and Puorto 1991. Mem. Inst. Butantan. 53:127–134). On 13 April 2012, we dissected an adult female *E. aesclapii* (CRLZ 000290; SVL = 69.21 cm, total length = 76.37cm; 102 g) collected at the Unilavras Biological Reserve – Boqueirão, Brazil (21.34638°S, 44.99083°W, datum WGS84; elev. 1250 m). In the stomach we found a young *Atractus pantostictus* (CRLZ 000345; SVL = 7.63 cm, total length = 9.29 cm; 1.47 g). Although *A. pantostictus* is common in the cerrado (savannah) region of Brazil it has not been previously recorded in the diet of *E. aesculapii*.

This work was licensed by IBAMA (Process n° 14740-1).

***LEPTOPHIS AHAETULLA* (Swordsnake). DIET.** *Leptophis ahaetulla* is a terrestrial and arboreal snake that feeds primarily on amphibians and secondarily on lizards, small birds, and small mammals (Albuquerque et al. 2007. J. Nat. Hist. 41:1237–1243; Vanzolini et al. 1980. Répteis das Caatingas. Academia Brasileira De Ciencias, Rio De Janeiro. 161 pp.). On 2 October 2011, at 1100 h, in the Estação Ecológica do Tapacurá (8.049°S, 35.221°W, datum: WGS 84; elev. 102 m), São Lourenço da Mata city, Pernambuco, Brazil, we observed a male *L. ahaetulla* (SVL = 93.6 cm) feeding on a male lizard, *Polychrus marmoratus* (Fig. 1; SVL = 13.7 cm). This is the first record of *P. marmoratus* in the diet of *L. ahaetulla*. Photographs of the predation event are deposited Paleoherpetological Laboratory of Universidade Federal Rural de Pernambuco, Recife, Pernambuco, Brazil (CHP UFRPE I001).

We thank the coordinator of the Estação Ecológica do Tapacurá for authorizing the research.

FIG. 1. *Leptophis ahetulla* ingesting a freshly killed *Polychrus marmoratus* in Atlantic forest of northeastern Brazil.

SÉRGIO LUIZ DA SILVA MUNIZ, CARINA CARNEIRO DE MELO MOURA, SOFIA FAJARDO VEGA, ALANE AYANA COUTO, JOSIVAN SOARES DA SILVA, EDNILZA MARANHÃO DOS SANTOS, GERALDO JORGE BARBOSA DE MOURA, Universidade Federal Rural de Pernambuco, UFRPE, Paleoherpetological and Herpetological Laboratory, Rua Dom Manoel de Medeiros, s/n, Dois Irmãos, CEP: 52171-900, Recife, Pernambuco, Brazil.

***LIOPHIS POECILOGYRUS* (Yellow-bellied Liophis). REPRODUCTION.** The colubrid snake *Liophis poecilogyrus* is broadly distributed in South America. Despite recent studies of its reproductive biology (Pinto and Fernandes 2004. Phyllomedusa 3:9–14; Vitt 1983. Herpetologica 39:52–66), no detailed data are available on hatchling size. Herein, we expand the knowledge on the reproductive biology of *L. poecilogyrus* through the record of hatchling morphometry.

At 1140 h on 12 May 2010, a clutch of 7 *L. poecilogyrus* eggs was collected in an urban area of Caucaia Municipality, state of Ceará, northeastern Brazil. The eggs were placed in a terrarium with a humid substrate of sand and leaf-litter, and maintained at room temperature in the laboratory of herpetology of the Núcleo Regional de Ofiologia da Universidade Federal do Ceará. The eggs averaged 2.83 ± 0.14 cm (range = 2.70–3.07 cm) in length and 1.60 ± 0.29 cm (range = 1.07–1.94 cm) in diameter, and all hatched within 24 h of collection. The newborn neonates measured 15.74 ± 0.44 cm (range = 15.10–16.30 cm) SVL; 2.71 ± 0.12 cm (range = 2.59–2.91 cm) tail length; and 2.82 ± 0.09 g (range = 2.64–2.91 g) mass. Hatchling voucher specimens were deposited in the scientific collection Coleção Herpetológica da Universidade Federal do Ceará (CHUFC 3550–3552).

***MICRURUS OBSCURUS* (Black-necked Amazonian Coralsnake). MAXIMUM SIZE.** The maximum size reported for *Micrurus* species based on an examination of the literature is 1602 mm (*M. spixii princeps*) and 1520 mm (*M. spixii martius*; Roze 1996. Coral Snakes of the Americas: Biology, Identification, and Venoms. Krieger Publ. Co., Malabar, Florida. 340 pp.). However, after examining specimens, Harvey (2003. Ann. Carnegie Mus. 72:1–52) concluded that these records were incorrect. Thus, the correct maximum total length for *Micrurus* is currently 1486 mm, based on a *Micrurus ancoralis ancoralis* from the Andes (Harvey, *op. cit.*). On 10 January 2012, at 1830 h, we found a freshly-killed female *M. obscurus* (SVL = 1480 mm; total length = 1555 mm) in Chácara de Jesus, Rio Branco, Acre, Brazil (9.911880°S, 67.767382°W, datum: WGS84; elev. 173 m). The habitat where the specimen was caught was secondary forest (capoeira) surrounded by pastures, agricultural land, and ponds. Our record exceeds the maximum recorded total length for the species by 210 mm (15%), and 69 mm (5%) for the genus. The specimen (UFAC 0380) was deposited in the herpetological collection at Universidade Federal do Acre. Fieldwork was funded by UNINORTE - Programa de Iniciação Científica and conducted under SISBIO permit n. 27290-1/2011.

***MICRURUS SERRANUS* (Coral Verdadera). DIET.** *Micrurus serranus* is a small coralsnake endemic to the inter-Andean dry valleys of Bolivia (Harvey et al. 2003. Ann. Carnegie Mus. 72:1–52). While most species of Bolivian coral snakes are distributed in lowland habitats, *M. serranus* generally occurs at higher altitudes, being found at elevations as high ~2750 m (Muñoz-Saravia et al. 2009. Checklist 5:510–512). Data on the diet of this species are lacking. Known prey of *M. serranus* are primarily snakes and amphisbaenians and include *Leptotyphlops striatulus*, *Amphisbaena cegei* (Harvey et al., *op. cit.*), *Lystrophis semicinctus*, and *Oxyrhopus* sp. (A. Langer, pers. comm.). Here we report a new snake species in the diet of *M. serranus*.

We dissected an adult female *M. serranus* (SVL = 545 mm, tail length = 35 mm) that was found dead on a dirt road (18.03°S, 64.15°W, datum WGS 84; elev. 1320 m) on 5 February 2011 in Florida Province, Santa Cruz Department, Bolivia. Inside the *M. serranus* we found an adult male *Apostolepis multicincta* (Dipsadidae; SVL = 290 mm; tail length = 40 mm) that had been ingested head-first (Fig. 1). This report confirms an additional snake species in the diet of *M. serranus*, providing further evidence for its ophiophagous feeding habits.

FIG. 1. Adult female *Micrurus serranus* from Florida Province, Santa Cruz, Bolivia. Protruding from the sides of the body of the *M. serranus* are the head and tail of an adult male *Apostolepis multicincta* that it had consumed.

Funding for this research was provided by the Senckenberg Natural History Museum of Frankfurt, Germany. CMS was supported by a National Science Foundation's Graduate Research Fellowship and the Applied Biodiversity Science NSF-IGERT Program at Texas A&M University (NSF-IGERT Award # 0654377).

***NAJA HAJE* (Egyptian Cobra). DIET / OPHIOPHAGY.** *Naja haje* is a large cobra (to 2.5 m total length) that is distributed across much of North Africa south to the Congo basin and east to Kenya and Tanzania (Trape et al. 2009. Zootaxa 2236:1–25). The diet of *N. haje* is based primarily on anecdotal data, suggesting the consumption of a variety of vertebrates (anurans, small mammals, small tortoises, lizards, small birds and their eggs, and occasionally snakes, including conspecifics; Schleich et al. 1996. Amphibians and Reptiles of North Africa. Koeltz Scientific Publishers, Koenigstein. 630 pp.; Trape and Mané 2006. Guide des serpentes d'Afrique occidentale. Editions, Paris. 226 pp.). Here we report two original observations of ophiophagy by *N. haje* in Dghoumes National Park, in southern Tunisia. The protected area consists of a halophytic zone merging with the Chott El Jerid, an intermediate plain of sub-desert continental steppe, marked by ephemeral watercourses (*wadis*), and a mountain chain to the north.

The first observation occurred at 0830 h on 20 September 2011. EF and an eco-guard discovered an adult *N. haje* (ca. 2

m total length) entwined with an adult female *Cerastes cerastes* (Horned Viper; SVL = 64.0 cm; tail length = 4.8 cm). Their arrival disturbed the snakes and the *N. haje* immediately released the *C. cerastes* and slipped into a bush. The partially paralyzed *C. cerastes* soon died and was preserved. The second observation occurred on 3 October 2011. Two eco-guards observed a recently killed *C. cerastes* surrounded by many snake tracks on the sand. Based on size and length, these tracks were likely from a cobra which we assume had been disturbed while preying on the viper. *Cerastes cerastes* is a specialized semi-fossorial snake that ambushes rodents and lizards while partially buried in soft sand (Young and Morain 2001. J. Exp. Biol. 205:661–665). Because this species is quite common in Dghoumes National Park, it may be a usual prey for an active predator like *N. haje*.

We thank Tim Woodfine (Marwell Wildlife), Gian Lorenzo D'Alterio (Ambulatorio Veterinario Farnese, Rome), Guy Parker (Marwell Wildlife), Abdelkader Chetoui (Dghoumes National Park), and all staff of Dghoumes National Park for their assistance. This research was supported and organized by Marwell Wildlife and sponsored by the Commissariat Régional de Développement Agricole (CRDA) Tozeur and the Direction Générales des Forêts (Ministère de l'Agriculture et des Ressources Hydrauliques - Tunis).

***NAJA KAOUTHIA* (Monocellate Cobra). REPRODUCTION / EGG SIZE.** *Naja kaouthia* is a non-spitting cobra that inhabits plains and mountains up to 700 m elevation throughout Thailand, Peninsular Malaysia, India, China, Myanmar, Laos, Cambodia, and Vietnam (Cox et al. 1998. A Photographic Guide to Snakes and other Reptiles of Peninsular Malaysia, Singapore and Thailand. New Holland Publishers, United Kingdom. 144 pp.). It also can be found in secondary forests and near human habitation (Ibrahim et al. 2008. The Common Amphibians and Reptiles of Penang Island. The State Forestry Department, Penang, Malaysia, 116 pp.). The total length of this species is up to 200 cm and the females can lay up to 45 eggs in a clutch (Cox et al., *op. cit.*).

On 4 December 2011, an adult female *N. kaouthia* (total length = 130 cm; 1700 g) was found dead (probably killed by villagers) near a paddy field at Kampung Anak Kurau, Taiping, Perak, Malaysia (4.562989°N, 100.470401°E, datum: WGS84; elev. <150 m). Dissection revealed 17 oval eggs that measured (mean ± SD) 5.72 ± 0.35 cm (range = 5.0–6.2) in length, 2.76 ± 0.14 cm (range = 2.5–3.0) in diameter, and weighted 27.94 ± 1.20 g (range = 26–30). The specimen (11USM-BK-NK01) was preserved and deposited at School of Pharmacy, Universiti Sains Malaysia.

We thank the Universiti Sains Malaysia, Penang for providing facilities and amenities. This project was funded by USM, Research University Grant no. 1001/PFARMASI/811156.

SHAHRIZA SHAHRUDIN, School of Pharmaceutical Sciences, Universiti Sains Malaysia, 11800 Penang, Malaysia; e-mail: shahriza20@yahoo.com.

***NERODIA CLARKII CLARKII* (Gulf Saltmarsh Watersnake). PREDATION.** *Nerodia clarkii* inhabits saltmarshes and coastal brackish waters along the Gulf Coast from Florida to Texas and on the northern coast of Cuba (Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Institution Press, Washington D.C. 668 pp.). Predators of *N. clarkii* likely include large carnivorous fish, large wading birds, *Agkistrodon piscivorus*, *Alligator mississippiensis*, and *Crocodylus acutus* (Ernst and Ernst, *op. cit.*), as well as large invertebrates such as crabs (Gibbons and Dorcas 2004. North American Watersnakes. Univ. Oklahoma Press, Norman. 438 pp.). To our knowledge, *Callinectes sapidus* (Blue Crab) represents the only previously published observation of a predation attempt on *N. clarkii* (Mohrman et al. 2008. Herpetol. Rev. 39:355–356).

PHOTO BY STEVE REISINGER

FIG. 1. Adult *Grus americana* (Whooping Crane) consuming a *Nerodia clarkii clarkii* at Aransas National Wildlife Refuge, Texas, in February 2012.

On 4 February 2012, an adult *Grus americana* (Whooping Crane) was observed and photographed (Fig. 1) consuming a *N. clarkii* at the Aransas National Wildlife Refuge, Aransas Co., Texas, USA (28.15294°N, 96.89620°W; datum WGS84). The crane consumed the snake headfirst after manipulating it for a short time. This observation represents the first documented vertebrate predator of *N. clarkii*. Diets of Whooping Cranes on wintering grounds in Texas mainly consist of Blue Crabs and clams, with other commonly reported prey items consisting of fish, snails, acorns, fruit of Carolina Wolfberry (*Lycium carolinianum*), and crayfish (Allen 1952. The Whooping Crane. Research Report 3, National Audubon Society, New York. 246 pp.; Hunt and Slack 1989. J. Wildl. Manage. 3:1150–1154). An *A. piscivorus* and unknown watersnake (possibly *N. clarkii*) were reported as prey items of Whooping Cranes in Texas (Allen, *op. cit.*). Understanding the diet of Whooping Cranes, especially when crabs and other common prey items are unavailable, such as during

droughts, will assist conservation efforts to protect habitats and associated prey items on wintering grounds and during migration.

We thank Steve Reisinger, Ed and Maxine Wehling, Martha Tacha, Linda Lanoue, Craig McIntyre, Curtis Schmidt, Brad Strobel, and Tommy Moore for assistance.

HARNER**, Platte River Whooping Crane Critical Habitat Maintenance Trust, Inc., 6611 W. Whooping Crane Drive, Wood River, Nebraska 68883, USA (e-mail: mharner@cranetrust.org).

***RHINOCEROPHIS AMMODYTOIDES* (Yararanata). DIET.** *Rhinocerophis ammodytoides* is a medium-sized pitviper endemic to southern Argentina (Carrasco et al. 2010. Amphibia-Reptilia 31:323–338). The diet of this species is known to include small vertebrates such as lizards and rodents (Cei 1993. Reptiles del Noroeste, Nordeste y Este de la Argentina. Herpetofauna de las Selvas Subtropicales, Puna y Pampas. Mus. Reg. Sci. Nat. Torino. 945 pp.; Martins et al. 2002. *In* Schuett et al. [eds.], The Biology of Pitvipers, pp. 307–328. Eagle Mountain Publ., Eagle Mountain, Utah). Here we report two novel lizard prey species for *R. ammodytoides*: *Pristidactylus scapulatus* (Leiosauridae) and *Liolaemus cf. ruibali* (Liolaemidae).

At 1500 h on 2 April 2012, we captured a subadult female *R. ammodytoides* (total length = 422 mm) in Quebrada Vallecito, Andes Mountains, Calingasta Department, San Juan Province, corresponding to pre-Andean limit of the occidental Monte Phytogeographic Region, Argentina (31.20°S, 69.28°W, datum WGS84; elev. 2860 m). The snake contained an obvious food item and dissection revealed a recently ingested *L. cf. ruibali* (SVL = 60 mm) and the posterior portion of a *P. scapulatus* (SVL ca. 70 mm) in the stomach (Fig. 1). Together, the prey totaled 15% of the snake's mass. The snake and prey were deposited in the Colección Herpetológica de la Universidad Nacional de San Juan (UNSJ).

RODRIGO GÓMEZ ALÉS (e-mail: coco16_90@hotmail.com), **MATIAS OLMEDO, ALEJANDRO LASPIUR, JUAN CARLOS ACOSTA, GUSTAVO FAVA,** and **ANA VICTORICA,** Departamento de Biología, Facultad de Ciencias Exactas, Físicas y Naturales. FIG. 1. *Rhinocerophis ammodytoides* from San Juan Province, Argentina, with two novel lizard prey, *Pristidactylus scapulatus* and *Liolaemus cf. ruibali.*

***SENTICOLIS TRIASPIS* (Green Ratsnake). DIET.** *Senticolis triaspis* is known to feed on small rodents, lizards, and birds (Reyna-Bustos et al. 2007. Anfibios y Reptiles del Bosque La Primavera. CUCBA, Gobierno de Jalisco. 125 pp.; Savage 2002. The Amphibians and Reptiles of Costa Rica: A Herpetofauna between Two Continents, between Two Seas. University of Chicago Press, Illinois. 934 pp.; Vázquez and Quintero 2005. Anfibios y Reptiles de Aguascalientes. CONABIO, CIEMA. 318 pp.). As with ratsnakes (*Pantherophis* spp.) and other semi-arboreal species, *S. triaspis* may inhabit caves where they presumably feed on bats (Schulz 1996. A Monograph of the Colubrid Snakes of the Genus *Elaphe* Fitzinger. Koeltz Scientific Books, Czech Republic. 439 pp.). Herein we report the first account of *S. triaspis* consuming a bat, *Eptesicus fuscus*.

On 12 August 2011, a juvenile *S. triaspis* was found in the municipality of Tuxcueca, Jalisco, Mexico (20.1397777°N, 103.1514444°W, datum WGS84; elev. 1635 m). The snake was crawling out of a hole in a wall full of bat refuges, about 2 m above the ground. When we captured the snake we detected the presence of a large prey item in its stomach and the snake subsequently regurgitated when placed in a bag. The recently ingested prey was identified as a bat, *Eptesicus fuscus* (Fig. 1). The wall bordered an ephemeral stream in tropical deciduous forest and was shared by other species of bats (*Artibeus hirsutus, A. jamaisencis, Tadarida brasilensis*, and another unidentified species).

FIG. 1. Prey item (*Eptesicus fuscus*) regurgitated by a *Senticolis triaspis* from Jalisco, Mexico.

***STEGONOTUS CUCULLATUS* (Slaty-grey Snake). DIET.** *Stegonotus cucullatus* is a colubrid snake native to the tropics of Papua New Guinea and Australia (Greer 1997. The Biology and Evolution of Australian Snakes. Surrey Beatty & Sons Pty Ltd., Chipping Norton. 358 pp.). The diet of *S. cucullatus* is varied, comprised largely of reptile eggs, but also includes insects, frogs, lizards, fish, and mammals (Brown et al. 2005. J. Trop. Ecol. 21:605–612; Greer, *op. cit.*; Trembath et al. 2009. Aust. J. Zool. 57:119–124).

A road-killed male *S. cucullatus* (SVL = 104 cm; total length = 124 cm) was collected at 1945 h on 19 May 2011 on the Arnhem Highway, in the tropics of the Northern Territory, Australia (12.65°S, 131.32°E; datum WGS84). On dissection its digestive

tract was found to contain a large (SVL = 11.81 cm) primarily undigested agamid lizard (*Amphibolurus temporalis*). Within its distribution, *A. temporalis* is similar in appearance to *Amphibolurus gilberti*, from which it was distinguished on the basis of dorsal scale keel orientation (Wilson and Swan 2003. A Complete Guide to Reptiles of Australia. Reed New Holland, Sydney. 480 pp.). The only species of agamid previously recorded as a prey item for *S. cucullatus* is *Diporiphora* sp. (Shine 1991. Copeia 1991:120–131). Because *S. cucullatus* is primarily nocturnal and a capable arboreal predator (Brown et al., *op. cit.*), and *A. temporalis* is diurnal and generally sleeps in trees, it is likely that *S. cucullatus* preys on these large agamids during their sleep.

CRYSTAL KELEHEAR, School of Biological Sciences, A08, University of Sydney, Sydney, New South Wales, 2006, Australia; e-mail: crystal.kelehear@hotmail.com.

***THAMNOPHIS EQUES* (Mexican Gartersnake). MORTALITY.** Abandoned, lost, or otherwise discarded fishing gear (ALDFG) represents a growing risk to aquatic environments. The ability of ALDFG to continue to fish (often referred to as "ghost fishing") has detrimental impacts on fish and other aquatic organisms (Macfadyen et al. 2009. Abandoned, Lost or Otherwise Discarded Fishing Gear. UNEP Regional Seas Reports and Studies, No. 185; FAO Fisheries and Aquaculture Technical Paper, No. 523. Rome, UNEP/FAO. 115 pp.). Here we report the death of two *Thamnophis eques* in abandoned fishing nets (ALDFG).

On 11 March 2012, during a visit to the shore of Lake Chapala near the pumping station in the Municipality of Chapala, Jalisco, México (20.311377°N, 103.142034°W, datum WGS 84; elev. 1530 m), we found two dead adult *T. eques* trapped in ALDFG (Fig. 1). Both individuals were located on the edge of a canal leading to the pumping station, a site commonly visited by local fishermen who usually fish with nets. On previous visits to the site we observed other organisms killed in abandoned fishing nets, mainly fishes but also several *Thamnophis melanogaster*. Further research is needed to determine the impact of the ALDFG in the local fauna of Lake Chapala.

FIG. 1. Two dead adult *Thamnophis eques* trapped in abandoned fishing nets at Lake Chapala, Jalisco.

We thank J. L. Navarrete-Heredia for his comments on the manuscript. JLB-R was supported by a scholarship by CONACYT for his Master's degree.

***THAMNOPHIS EQUES MEGALOPS* (Northern Mexican Gartersnake). PREDATION.** Documented instances of fish preying on snakes are generally rare and the extent to which these events affect local populations is unknown. Recent records including a brown trout preying on *Pituophis catenifer* in Utah, USA (Wamback and Engemen 2011. Herpetol. Rev. 42:618–619), a Rainbow Trout with a *Notechis scutatus* in its stomach in Australia (Clear 2011. Herpetol. Rev. 42:442–443), and a Longnose Gar attacking *Pantherophis spiloides* in Illinois, USA (McCallum et al. 2011. Herpetol. Rev. 42:443), demonstrate that a variety of fish species likely prey on snakes when provided the opportunity. Predators such as nonnative fishes, in combination with other threats, have undoubtedly contributed to the decline of *Thamnophis eques megalops* populations throughout all or portions of its range (U.S. Fish and Wildlife Service 2008. Fed. Reg. 73:71778–71826). One nonnative predator, *Micropterus salmoides* (Largemouth Bass), will apparently prey on "any moving thing small enough to swallow" (Minckley 1973. Fishes of Arizona. Arizona Game and Fish Dept., Phoenix, Arizona. 293 pp.), however, we are aware of few instances of bass preying specifically on gartersnakes (Hodgson and Hansen 2005. J. Freshwater Ecol. 20:793–794),

PHOTO BY DON ALTRINGER

FIG. 1. Largemouth Bass (*Micropterus salmoides*), attacking an adult *Thamnophis eques megalops* at Bubbling Ponds Hatchery, Arizona, USA. The bass in the foreground is indicated with a black arrow, and has swallowed much of the posterior half of the snake, while another bass can be seen behind the snake.

despite the apparent assumption that it occurs relatively commonly (U.S. Fish and Wildlife Service, *op. cit.*). Here we describe two instances of predation by Largemouth Bass on *T. eques* that we documented during a study of the gartersnakes at Bubbling Ponds Fish Hatchery, Yavapai Co., Arizona, USA (34.765°N, 111.895°W; datum NAD83).

Largemouth Bass maintained in a single, earthen pond at the hatchery average 1.3–1.8 kg (400–500 mm standard length), with some larger individuals reaching over 2 kg. At 1030 h on 16 July 2010, we witnessed a neonate *T. eques* enter the pond, startled off the bank by our approach. Immediately, a Largemouth Bass engulfed the snake. After momentarily releasing the snake, the bass bit it again and appeared to swallow the snake. At 1000 h on 22 June 2011, a visitor to the hatchery observed a Largemouth Bass attacking the tail of an adult (ca. 600 mm total length) *T. eques* (Fig. 1). The snake struggled to continue swimming for ca.15 min. Eventually it was dragged under water, after which several other bass attacked it as well, and the snake was not seen again. Although the frequency with which bass prey on snakes appears to be low (J. R. Hodgson, pers. comm.), the implications of these observations for conservation of *T. eques* are clear; conversion of aquatic habitats to impoundments stocked with bass has the potential to seriously affect small local gartersnake populations.

We thank Don Altringer for providing the photo and detailed account of one of the predation events, and James R. Hodgson for additional information on bass diets.

MEGAN E. YOUNG (e-mail: megan.e.young00@gmail.com), and **VALERIE L. BOYARSKI** (e-mail: vboyarski@yahoo.com), Nongame Branch, Arizona Game and Fish Department, 5000 W. Carefree Highway, Phoenix, Arizona 85086-5000, USA.

***THAMNOPHIS GIGAS* (Giant Gartersnake). MOVEMENT.** *Thamnophis gigas* historically inhabited marshes in the Central Valley of California, but currently inhabits rice fields and their supporting infrastructure of canals in the Sacramento Valley (northern portion of the Central Valley). Because of extensive habitat loss, *T. gigas* is listed as Threatened by the State of California and the U.S. Fish and Wildlife Service. Existing populations of *T. gigas* are often fragmented by inhospitable habitats (uplands, forests, most agriculture) and roadways. We report the movement of an individual *T. gigas* across a busy highway, and suggest that movement occurred through a culvert.

On 8 July 2010, one of us (ECH) captured, marked, and released a small (SVL = 362 mm; mass = 30 g) female *T. gigas* 349 m east of California Highway (CA Hwy) 99 in Sacramento Co., California, USA. On 5 July 2011, the same individual was recaptured 928 m to the west of the original capture location (579 m west of CA Hwy 99; Fig. 1). The individual had grown 263 mm and gained 104 g in the intervening year. She was subsequently captured on 6 July 2011, 99 m east of her location on 5 July 2011, and again on 7 July 2011, 133 m east of her location on 6 July 2011 (Fig. 1). She might represent a young female dispersing to establish a stable home range.

The snake's movement across CA Hwy 99 is significant because of the volume of traffic on and characteristics of CA Hwy 99 and characteristics of the box culvert through which the individual likely passed. CA Hwy 99 consists of four lanes of traffic (each direction is paved for a width of 13 m) separated by an 11 m median consisting of herbaceous vegetation. To the east, the road is bordered by 28 m of herbaceous vegetation, then a 9-m wide canal oriented north-south, with about 10 m between the east bank of this canal and the end of the east-west canal in which the individual was initially captured. A small (approx. 0.6 m diameter) cylindrical culvert connects the east-west canal to the north-south canal. To the west, CA Hwy 99 is bordered by 23 m of herbaceous vegetation, then a 5 m wide canal oriented north-south, with about 18 m between the west bank of this canal and the end of the east-west canal in which the individual

FIG. 1. Observations (yellow dots, with dates), locations of culvert openings (black stars), and potential movement paths (red lines; solid = culvert passage, dashed = direct overland route) of *Thamnophis gigas* #1461. Note that 2010 and 2011 observations are bisected by California Highway 99.

FIG. 2. The 1.8 m x 1.8 m box culvert 89 m long through which *Thamnophis gigas* #1461 likely passed. The culvert is located 1.2 km south of the east-west canal in which the individual was captured.

was subsequently captured. *Thamnophis gigas* are highly aquatic and rarely move more than a few meters from aquatic habitats (USGS, unpubl. data), so the total overland distance of 130 m (including the 14 m of north-south canals) itself represents a substantial barrier to movement.

In addition to the distance over which upland movements would have to occur, CA Hwy 99 has very high traffic volumes. In 2002, average annual daily traffic volume was 41,000 vehicles (CA DOT; www.dot.ca.gov). This volume of traffic is nearly four times that reported for US Hwy 441 in Florida, where culverts and barrier walls were constructed to reduce mortality of small vertebrates (Dodd et al. 2004. Biol. Conserv. 118:619–631). It is likely that residential and commercial development in the Natomas Basin have substantially increased traffic volumes since 2002. The high volume of traffic and great width of CA Hwy 99 make it highly unlikely that the individual crossed the road's surface.

If the individual did not cross over the road's surface, it could have crossed under CA Hwy 99 through culverts located 1.2 km south or 1.6 km north of the canal in which the individual was captured. The culvert to the south was a single box culvert approximately 1.8 m wide x 1.8 m tall x 89 m long, with an approximate water depth of 0.2 m and air clearance of 1.6 m (Fig. 2). Use of this culvert would imply a net movement of 3.3 km over 362 days. The culvert to the north was a double box culvert, with both passages measuring 2.1 m wide x 2.1 m tall x 102 m long. In contrast to the south culvert, these culverts are located near a pumping station, and were nearly filled with water (20 cm air space on 1 May 2012). Use of these culverts would imply a net movement of approximately 4.1 km. Because of the shallower depth and slower movement of water, greater light penetration, greater air space, and closer proximity to the canal in which the individual was captured, we suggest that the individual more likely passed through southern culvert than the northern culverts.

The characteristics of ideal culverts for wildlife crossings (wide, short length, allowing the penetration of light, and with fences to direct movement away from the road and into the culvert; Yanes et al. 1995. Biol. Conserv. 71:217–222.; Woltz et al. 2008. Biol. Conserv. 141:2745–2750) are in marked contrast to the long, narrow box culvert through which the individual likely passed. If individual *T. gigas* pass through culverts of this type and length, it is likely that bridges and culverts of shorter length or greater width would allow, at a minimum, genetic connectivity among populations separated by roadways. Examining the probability of use of culverts of different characteristics and enhancing culverts to improve passage rates of *T. gigas* will promote gene flow and could maintain demographic connectivity among otherwise fragmented populations.

***THAMNOPHIS VALIDUS CELAENO* (Baja California Gartersnake). ARBOREALITY.** Terrestrial and arboreal habitats differ in the type and amount of prey they offer, vulnerability to predation, and in physical factors such as temperature and humidity. Many snake species are highly specialized for either terrestrial or arboreal life and rarely exploit alternative habitats (Shine et al. 2005. J. Therm. Biol. 30:179–185). However, some taxa display ontogenetic shifts in habitat use or use a broader range of habitats on occasion (Shine et al. 2002. Ethology 108:897–910). Species in the genus *Thamnophis* are primarily terrestrial, although some species occasionally climb in vegetation. For example, *T. sirtalis parietalis* (Red-sided Gartersnakes) use arboreal habitats to access higher temperatures than those available on the ground (Shine et al. 2005, *op. cit.*). *Thamnophis validus* is a semi-aquatic species with a fragmented distribution in the water systems of the Cape Region, Baja California Sur, México (Grismer 2002. Amphibians and Reptiles of Baja California, including its Pacific Islands and the Islands in the Sea of Cortes. Univ. California Press, Berkeley. 399 pp.). *Thamnophis validus* is primarily nocturnal, which distinguishes it from many other gartersnakes (Rossman et al. 1996. The Garter Snakes: Evolution and Ecology. Univ. Oklahoma Press, Norman. 336 pp.), and is strongly tied to aquatic habitats (De Queiroz et al. 2001. Copeia 2001:1034–1042). Herein we report the first account of arboreal habitat use for *T. validus celaeno*.

FIG. 1. *Thamnophis validus celaeno* in El Chorro, Agua Caliente, Baja California Sur, México, *in situ*, exhibiting arboreal behavior.

On 30 August 2011, at 2045 h (air temp. = 28.7°C), we observed a juvenile female *T. validus celaeno* (SVL = 213 mm; total length = 286 mm; 7.5 g; cloacal temp. = 32.9°C) 40 cm above the ground in *Ambrosia monogyra* vegetation (Fig. 1) along the margin of a pond in El Chorro, Arroyo Agua Caliente, Baja California Sur, México (23.43996°N, 109.80757°W, datum: WGS84; elev. 182 m). This species has also been seen climbing on *Typha dominguensis* at this same locality and on *Baccharis salicifolia* in Cañon de la Zorra (A. Cota pers. comm.), both localities on the eastern slope of the Sierra de la Laguna, Baja California Sur. Because *T. validus* feed primarily on aquatic prey, we suggest that this may be a thermoregulatory behavior.

We thank to Raymundo Dominguez for plant identification, Abelino Cota and Franco Cota for their help in field and comments, and Diana Dorantes for English editing.

JAY M. SAVAGE
Department of Biology, San Diego State University
San Diego, California 92182-4514, USA
e-mail: savy1@cox.net

At the First World Congress of Herpetology (1989) all delegates were presented with an amazing book relating to the history of herpetology containing sections by Kraig Adler (Herpetologists of the Past), John S. Applegarth (Index of Authors in Taxonomic Herpetology), and Ronald Altig (Academic Lineages of Doctoral Degrees in Herpetology). It was the talk of the meetings and provided hours of consultation during the following years. In 2007, on the occasion of the celebration of the golden anniversary of the founding of the Society for the Study of Amphibians and Reptiles, the same authors produced a follow-up of 389 pages. It was again an exciting and scholarly insight into the history of herpetology with many new biographies added by Adler and updates and expansion of their sections by Applegarth and Altig. The present volume is the third iteration in the series by Adler, Applegarth, and Altig, issued at the Seventh World Congress of Herpetology held at the University of British Columbia in August, 2012. We all must be grateful to these authors for providing the herpetological community with these in-depth treatments of the people who made herpetology what it is today. There is no other sub-discipline of zoology that can boast of a similar wide-ranging, detailed, and original coverage of the majority of figures that have contributed to our field, from Nicander of Colophon (ca. 197–130 B C.) to John T. Thorbjarnarson (1957–2010 A.D.).

The Herpetologists of the Past is the longest section and, as in the previous two volumes, is worldwide in coverage providing a biography, portrait, and signature of each treated subject (N.B.: In a very few cases signatures or portraits were unavailable). In addition, there are short sketches of individuals mentioned in the main biographies but without the accompanying portrait or signatures, usually in the endnote following a biography. Biographies are clustered around the time period when the covered individual was active in herpetology. For the period 1820 to 1960, the clusters are for half decade timeframes (e.g., 1820–1825) but by decade thereafter. Many other herpetologists are mentioned in the context of their relationship to the individual covered by the main biography. The biographies in this section bring to 786 the individuals covered in the main biographies in the series. As in earlier volumes no living herpetologists are included. I note that as the series progressed the average biography became longer with an increasing depth of coverage of the subject's contributions.

While the two earlier volumes, because of the trajectory of the development of the field, included mostly European and American scientists, Volume 3 has extensive biographic essays on Russian, Japanese, Chinese, Indian, and Brazilian herpetologists, among others. It also provides a significant coverage of pre-Linnaean contributors to our field. The fuzzy limits of who is a herpetologist have also been expanded between 1989 and 2012. Of course the early workers, at least in the post-Linnaean period, were frequently medical doctors and usually would have considered themselves to be both physicians and naturalists. The notion of a separate sub-discipline of herpetology was a 20th century construct. I think that a number of folks portrayed from later periods, especially in the late 19th and 20th centuries would have called themselves an embryologist, physiologist, geneticist, etc., rather than a herpetologist. However, their inclusion provides a significant historical context to the entire section. The Herpetologists of the Past concludes with a comprehensive index to all names of herpetologists in the biographies and the mini-biographies, and names of all herpetologists mentioned in the body of the main accounts. Adler notes his sections provide a basis for a comprehensive history of herpetology, one that I could imagine being like the classic *Ornithology from Aristotle to the Present* by Erwin Stresemann (1975). Kraig, maybe it's about time you started on it.

When I first started in herpetology there were probably less than 250 herpetologists worldwide. Almost everyone was exchanging publications and corresponding with one another, often by handwritten correspondence. Almost every one of these colleagues is included in one of the three Adler volumes. In those days annual meetings of the American Society of Ichthyologists and Herpetologists would have a couple hundred attendees. Now there are so many in the field that we have become extremely specialized with few having a broad knowledge across geographic and many taxonomic boundaries. Perhaps the last herpetologist with worldwide knowledge akin to that of the Dumérils and Bibron, Boulenger, and Cope was Robert Mertens, who personally collected and published on amphibians and reptiles from every continent except South America. However, it

is clear with the many intellectual and technological advancements of recent years (e.g., cladistic analysis, computers, GPS, PCR, genomics, tomography, etc.) that the present century is a golden age for our field of study. Adler's Herpetologists of the Past provides a reminder of the notable achievements of our predecessors who made extraordinary contributions to the framework of herpetology and provided the foundation for all future research.

The second section, The Index of Authors in Taxonomic Herpetology, has been extensively revised and expanded from the two earlier iterations. It now contains 5,290 names, double the number listed in Volume 2. The list consists of the full name of the individual, dates, country of residence, and the order or orders of amphibians and reptiles for which the individual has published a new genus-group or species-group name. Also listed are the same data for all herpetologists who have had one or more taxa within the living orders of amphibians and reptiles named for them and have published at least one herpetological paper. This list happily includes many extant herpetologists. As acknowledged by the author, this is a list in progress because it was not always possible to ascertain details of all relevant entries about an individual from existing sources. He encourages all readers who have additional information to contact him as he plans a continuous update. Hopefully this may be set up as a website.

The third section on Academic Lineages is completely updated and expanded and contains 57% more entries than the 2007 version. It includes the names of each herpetologist who was the professor/mentor to one or more doctoral students. The information is arranged by series within a particular country so that succeeding derived generations can be followed both forward and backward. The section contains 5,562 names. The most populated lineage in the list is from Louis Agassiz through his students and their students to form 273 separate doctoral lineages consisting of 1,461 descendents. Agassiz was a student of Lorenz Oken but also identified himself with Alexander von Humboldt with whom, one might say, he did a post-doc at the Paris Museum. The association of the two is made clear by the placement of life-sized statutes of these two giants of biology on the second-story facade of Jordan Hall, the original biology department building at Stanford University, by the university's first president David Starr Jordan. Jordan is listed as a student of Agassiz in Altig's treatment. Because of Agassiz' preeminence as the founder of this lineage the majority of herpetologists active in the United States today are academic cousins. This section concludes with an index to all names for ready reference.

There is, of course, a serious problem with this great work. Once one opens it to read a biography, check on a taxonomic herpetologist, or follow an academic lineage, one can't put it down because the next page and the one after that are so inviting! That having been said, everyone reading this review should have a copy of the *Contributions* in their library, preferably near their desk as an essential reference and a reminder of the history that underpins our own ongoing contributions to herpetology.

Senckenberg Forschungsinstitut und Naturmuseum Frankfurt, Senckenberganlage 25, 60325 Frankfurt am Main, Germany
e-mail: slotzkat@senckenberg.de

The Frankfurt Contributions to Natural History ("Frankfurter Beiträge zur Naturkunde") series has been equipping amateur as well professional herpetologists with fine field guides for nearly two decades. Depending on their particular scope, these mostly handy books allow for the identification of all known members of discrete taxa (single families, frogs, lizards, reptiles, etc.) or the entire herpetofauna of the treated territory. Books in this series feature a black silhouette map of the region under consideration on a white cover. Volume 45 of "the white series" is dedicated to the easternmost of the Mediterranean Sea's large islands, Cyprus. The team of authors is nicely heterogeneous in every aspect. Whereas the German senior author was an undergraduate student of biology and philosophy in his early twenties at the time of publication, his co-authors are more than 40 years older—a British photographer with a PhD in chemistry and an expatriate Austrian residing and running a reptile park on Cyprus. However, all three share a passion for amphibians and reptiles and have a long familiarity with the island.

As the Minister of Agriculture, Natural Resources and Environment of the Republic of Cyprus points out in his foreword, the book "fills a long-standing need." In their following preface, the authors specify that this need is two-fold, as addressed by the scope of their work. The first aim is to summarize existing knowledge of the Cypriot herpetofauna which, according to them, has received little scientific attention in the past. The book's second purpose is to provide a solid source of information as well as an identification guide for the non-expert and especially the island's residents.

The Materials and Methods section concisely outlines the scope of the different sections of the species accounts and elucidates the sources and processing of the data presented. Before listing the abbreviations used in the text, the authors briefly but thoroughly justify the exclusion of certain doubtful species records from Cyprus (e.g., *Zootoca vivipara*) mentioned by previous workers.

The two-fold approach pursued by the authors manifests itself in the subsequent introduction, the first part of which is dedicated to Cyprus itself. The reader is familiarized with the island's geography, geology, and tectonic history, aided by physical and political maps as well as photographs of major geological units. Likewise, the section on climate and vegetation is

complemented by representative pictures of its four major vegetation types, for which typical plant species are listed, and by a brief summary of the island's botanical diversity and endemism. Clearly directed at the non-herpetologist, the introductory chapter's second half provides a short course on herpetology, spanning the history of herpetology and systematics, the principles of classification and taxonomy, the evolution of amphibians and reptiles as well as aspects of their ontogeny, anatomy, physiology, sensory perception, behavior, vocalization, and reproductive and feeding strategies. Here the authors have successfully managed to condense a great an amount of meaningful information into just twelve pages while both maintaining a coherent flow of ideas and keeping the highly concise text perfectly intelligible to the layman.

Species accounts for three anurans and 27 reptile species occupy more than two thirds of the book. Preceding their respective specific accounts, the alphabetically arranged orders and families are each briefly characterized. With the exception of shorter accounts for five species whose records from Cyprus require substantiation (*Eirenis levantinus, Natrix tessellata, Platyceps najadum*) or which have been introduced by man (*Trachemys scripta* and *Testudo* spp.), all species accounts are adequately detailed and consistently organized. For widespread taxa, the information presented explicitly refers to the Cypriot populations when available.

The scientific name, author, year of publication, and English common name(s) comprise the headline for each account and are followed by common names in Greek and Turkish. Starting with the first historical mention of the species from the island, the paragraph on taxonomy details the taxonomic history of its populations on Cyprus, thereby discussing nomenclatural changes and their applicability to the Cypriot populations in detail, usually down to the subspecies level. A short diagnosis defines the population, endemic subspecies, or endemic species found on Cyprus; i.e., this paragraph is not intended for distinguishing a Cypriot specimen of a certain species from specimens of other species found on Cyprus, but rather from non-Cypriot specimens of the same, or a closely related, species.

An additional detailed description of external morphology and coloration will allow for a reliable identification of any amphibian or reptile encountered on the island. However, in most cases where the animal in question is alive and complete, the reader will not have to consult it in full, given the brilliant photographs illustrating different color variants, morphological details and, where relevant, developmental stages, of every species. On the other hand, the professional reader will be delighted by the detailed characters of scalation and even more by the fine head drawings provided for seven lizard and seven snake species.

The altitudinal distribution on Cyprus of each species is delineated along with its entire geographic range. A clear point distribution map combines locality records from a handful of key publications listed in the Materials and Methods chapter with those from the large dataset generated by the authors during their own field studies. A minor drawback of these maps is that the contours indicated (determined by me to be at 300, 700, and 1300 m asl) are not mentioned anywhere. A "Biogeographic classification" section assigns each species to a zoogeographical subregion of the Palaearctic.

A paragraph on ecology details the habitat(s) occupied by the species on Cyprus and varied aspects of its life history, such as seasonal activity patterns, reproduction, prey, predators, abundance, and population ecology. Syntopic occurrences with other herpetofaunal species are listed along with present threats and conservation status. The concluding section on behavior merges mostly rather general behavioral traits reported from the literature with numerous specific observations made by the authors.

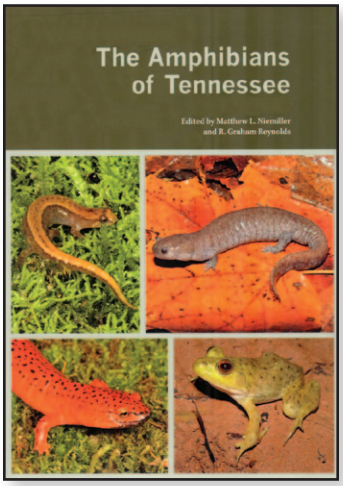
The species accounts as a whole, and especially their sections on distribution, ecology, and behavior, benefit greatly from the combined long-term experience of the three authors with the island and its herpetofauna. Luckily, cameras must have been at hand throughout their field trips, as photographs of mostly superior quality illustrate many ecologically and behaviourally salient points, in addition to the more standard portrait and habitat shots. Typical examples include defensive postures and actions, utilization of different substrates, and a variety of predation events.

The fourth chapter presents a brief zoogeographical analysis that reveals that a large fraction of the species belong to the Eastern Mediterranean and/or Irano-Turanian regions as defined by the authors. Furthermore, three species and eight subspecies are currently regarded as endemic to Cyprus. Apart from a short discussion of possible cases of island dwarfism and gigantism among the Cypriot herpetofauna, the authors summarize published information on divergence time estimates and compare these to the island's geological history. Discussing different immigration times and scenarios, they reach the conclusion that both overland (during the Messinian Salinity Crisis) and oversea dispersals have contributed to the current herpetofaunal assemblage. Pointing out the few dating approaches that have been undertaken to present, as well as several indications of faunal divergences between the island's two separate mountain systems, they pinpoint open questions and delineate possible directions for future research.

Subsequently, a short chapter provides examples how the herpetofauna—mostly reptiles—have influenced human culture on Cyprus. In turn, the book's last chapter is concerned with the opposite relationship; after identifying the principal threats that Cypriot amphibians and reptiles currently face, all of which are linked to anthropogenic activity, the authors summarize existing conservation legislation and programs as well as the state of environmental education, inevitably concluding that much remains to be done for the conservation of the island's terrestrial herpetofauna, especially the three taxa which they regard as most seriously threatened: *Mauremys rivulata, Hierophis cypriensis,* and *Natrix natrix cypriaca.*

A twelve-page glossary assures that not a single non-herpetologist will be left wondering about the meaning of any technical term, twenty-two pages of references provide the interested reader with every opportunity for further reading, and a systematic index helps to locate mentions of organism as well as place names. Last but not least, the book is completed with two fine appendices: Appendix I provides a polytomous identification key in full-phrase question style that focuses on easily detectable features of external morphology and usually offers several characteristics per question. As the key is explicitly directed at the non-specialist, the trade-off of the greater precision and efficiency of a "professional" key for increased intelligibility can be seen as a successful strategy. Appendix II deals with snakebite on Cyprus, and does so excellently. Its first part very clearly contrasts the bites of Cypriot colubrids with those of the native viper and separates misbelief from reality and the second part gives reasonable step-by-step advice for first aid after a viper bite, including Cypriot emergency and hospital phone numbers.

In conclusion, *The Amphibians and Reptiles of Cyprus* is more than a field guide to 30 species inhabiting an island. It is also



more than a summary of scattered publications on these species. Much more, it is the best possible result of a profitable alliance of three passionate connoisseurs of a micro-continent somewhere between southwestern Asia and southeastern Europe and its herpetofauna. From another perspective, it is a prime example of how a sophisticated treatment of a geographically restricted herpetofauna may be realized. The book seems to contain virtually every bit of knowledge generated so far on any aspect of the amphibians and reptiles of Cyprus and should be an equally valuable source of information for the herpetologist (amateur or professional), the conservationist, the local resident, and the visitor with an interest in wildlife. Simultaneously, its portability and durable binding certainly qualify it for real-life use outside of hotel rooms or libraries. If Cyprus is on your travel agenda, this hybrid between reference work and field guide should be on top of your packing checklist. No wonder a second edition is in preparation for 2013.

The Amphibians of Tennessee

edited by Matthew L. Niemiller and R. Graham Reynolds. 2011. University of Tennessee Press, Knoxville, Tennessee (www.utpress.org). Hardcover. 369 pp. US $39.95. ISBN 978-157233-762-6.

VINCENT R. FARALLO
Ohio University, Department of Biology
107 Irvine Hall, Athens, Ohio 45701, USA
e-mail: vfarallo@gmail.com

In the United States, Tennessee has one of the highest levels of amphibian species richness and diversity, including many endemics. Furthermore, Tennessee has a wide range of ecoregions, from the Mississippi Alluvial Plain on the western border, with a high average annual temperature and an overall low elevation, to the Blue Ridge Mountains at the eastern edge, with low average annual temperatures and overall high elevation. This gradient of ecoregions across the state allows for the great diversity of amphibian species. Until this book was published, the primary guide to amphibians of Tennessee was the *Atlas of Amphibians in Tennessee* (Redmond and Scott 1996), which—as an atlas—provided primarily distributional data and gave only short descriptions without photos or keys. Although this book is available online (www.apsu.edu/amatlas/), changes to taxonomy and increased research on amphibians of Tennessee certainly warranted an updated and more extensive publication on the topic. Other quality guides are available for amphibians in Tennessee such as *The Amphibians of Great Smoky Mountains National Park* (Dodd 2004), but no up to date field guide covers the entirety of the state and the diversity of habitat types it encompasses.

The book appears to be well constructed, with flex binding that keeps the book light but still durable. As of this writing, I have been abusing it for two months, including taking it on a field trip to the Cherokee National Forest and the Great Smoky Mountains National Park, and it has yet to show any real damage. A casual flip through the book reveals many gorgeous photographs. All species accounts contain multiple photos, including a larval representative when appropriate. Similarly, the aesthetically pleasing design of the book highlights important information while also making it easy to navigate for amateur and professional herpetologists alike.

The Amphibians of Tennessee is similar to many other guide books in that it is broken into several parts. The first part contains information about habitat, conservation issues, and general amphibian knowledge. Niemiller and Reynolds do a great job detailing amphibian biology, including large easy to interpret photographs of important morphological characters and diagrams of the typical measurements taken on specimens. Much of the general information on amphibians will be too basic for a seasoned herpetologist to benefit from, but it is by no means trivial and will certainly benefit the people new to the study of amphibians or those simply wanting to know more about local wildlife. The editors also present an informative section of the physiography, climate, and habitats of Tennessee, with many useful maps and photographs. As with any field guide there is also a section on finding amphibians in Tennessee. This will be especially useful for people just beginning in herpetology, especially as it makes people aware of the existence of local, state, and federal laws that govern collecting activities. Furthermore, this section also strongly highlights the importance of returning cover objects to their original position, certainly a good habit for all young field herpers to develop and one that even some of the most experienced need to be reminded of from time to time. The second and third parts of the book comprise species accounts of salamanders and frogs, respectively. Each account section begins with a map displaying the number of species per county and a taxonomic key for that particular group. The key is immediately followed by the species accounts, ordered alphabetically first by family, then by genus and species. Each account contains seven (salamanders) or eight (frogs) subsections, a map of the species' range in Tennessee, and several photographs. The subsections are standard for field guides and are presented in the following order: 1) a basic description of the species, 2) the etymology of the scientific name, 3) similar species, focusing on species one might see in Tennessee, 4) distribution, again with focus on their range in Tennessee, 5) habitat in which the species is found, 6) natural history, including reproduction, diet, potential predators, etc., 7) vocalization (anurans only), and finally, 8) conservation status. At the end of the book, following the species accounts, there is also a section covering species which have been reported to occur in Tennessee but remain unverified. This information can be especially useful when an animal is found but does not match the description of any of the native species. The editors also included a checklist of the amphibians of Tennessee and a list of additional readings on select topics. Finally, the book also contains a comprehensive glossary.

An additional feature, spread throughout the text, and my favorite component of this publication, is the field notes sections. These are 1–2 page narratives of interesting experiences the editors have had while searching for amphibians in Tennessee. These stories are great for generating interest in amphibians and instilling a lifelong passion for wildlife. I will always remember the first time I witnessed a spring migration of amphibians to breeding ponds in northern Ohio; it was an experience that

helped solidify my interest in herpetology. Reading the field note accounts in *The Amphibians of Tennessee* elicits a similar response and makes me want to get out in the field to look for amphibians.

I only have a few small criticisms of the book. The size of the book is both a pro and con. At approximately 7 inches wide and 10 inches tall, the editors were able to include a large amount of information while still maintaining a very clean and uncluttered design. They were also able to include large photographs to illustrate morphological characters. Larger photos were also ideal because they highlight the quality of the photographs used in the book as even stunning photographs can seem mundane when shrunk down. However, the books dimensions make it less ideal for field situations. I already know this book will be a fixture in my vehicle, but I am probably less likely to want to carry it out into the field with me. Furthermore, the range maps for the species accounts were used to display both the species range and specific counties in which verified specimens have been documented. However, I found that the colors utilized made it difficult to readily distinguish between the two. I would have liked to see a range map accompanied by specific points that species have been found. Additionally, as a herpetologist who works in multiple states, I would have liked to see a small inset map of the species entire range, similar to the ones found in *Salamanders of the Southeast* (Mitchell and Gibbons 2010). Finally, as this book is aimed at amateur through professional herpetologists, the taxonomic keys may be difficult to follow for some people. The figures accompanying the taxonomic keys were very helpful, but additional photos and figures would have made the keys even more useful. Additional photos of larval salamanders and tadpoles might also have been helpful, especially close ups of tadpole mouths in the species accounts. However, most of these criticisms reflect personal preference and do not detract from the quality of the book.

Overall, this is a great field guide both in terms of the content and aesthetics. The information presented in this book will be useful to people of all experience levels. The editors do a good job of instilling interest in the reader and highlighting the diversity of amphibians found in the state through both their narrative and the use of superb photographs. I certainly recommend this book to anyone who plans on searching for, or simply learning more, about the amphibians of Tennessee.

by Jean-François Trape, Sébastien Trape and Laurent Chirio. 2012. IRD Éditions, Marseille, France (www.ird.fr/editions). 503 pp. Softcover. EUR 64.00 (approximately US$ 80.50). ISBN 978-2-7099-1726-1.

OLIVIER S. G. PAUWELS*
PHILIPPE J. R. KOK
Département des Vertébrés Récents
Institut Royal des Sciences naturelles de Belgique
Rue Vautier 29, 1000 Brussels, Belgium
**Corresponding author; e-mail: osgpauwels@yahoo.fr*

Although a number of papers and a few books deal with the non-ophidian reptile fauna of West Africa, they all focus on a limited region or taxonomic group, and the taxonomic and ecological information on numerous genera is outdated in many of these works. This new book by Trape et al. not only is the first book providing an extensive overview of all non-ophidian West African reptiles, but it does it in an exceptional way, at a level of documentation rarely achieved in any African reptiles book. It covers all lizard, turtle and crocodile species in the 15 West African countries, as well as Chad, the Saharan areas of Morocco ("Sahara occidental"), Algeria and Tunisia south of 32°N, and Lybia except its littoral area.

The genesis of the present book, only briefly mentioned in the book itself, is worth explaining here. Borreliosis was a nearly totally unknown disease in West Africa and Sahara when Sébastien, Jean-François Trape's son and second author of the opus, contracted it during a field trip in 1989. It took three months for Jean-François to diagnose Sébastien's disease, while the latter had already gone through seven high fever episodes. Jean-François eventually published a medical record of his son's borreliosis case and later of more and more other cases he diagnosed in other patients. This poorly known disease actually turned out to be the second most common cause for fevers in Senegal, after malaria (Trape et al. 1991). From 2002 J.-F. Trape conducted intensive field researches on this disease in western, central and northern Africa. J.-F. Trape was not at all a specialist of lizards until he began that research program in 2002 (J.-F. Trape, pers. comm., Sept. 2012). But he took this unique opportunity of visiting between 2002 and 2011 a large number of localities, often extremely remote, in 16 African countries, to observe, photograph and collect lizards and other reptiles, as a by-product of his medical research. About 6,500 specimens were collected during these surveys. Sébastien, whose Ph.D. dissertation was on the Mugilidae of West African coasts, specialized in fish and reptiles and in molecular biology, the latter specialty having proven very useful for the numerous taxonomic changes, resurrections, synonymies and new species descriptions included in the book.

The binding and paper of the book are of excellent quality. The front cover of the book is illustrated by a photograph of a *Chamaeleo gracilis* (without locality; it was actually taken near Kpalimé, Togo; J.-F. Trape, pers. comm., Aug. 2012). Main parts of the book include a geographical introduction (pp. 11–21), an introduction to the herpetofauna treated (pp. 23–59), identification keys to families, genera and species (pp. 61–121), lizard species accounts (pp. 123–417), crocodile species accounts (pp. 419–425), turtle species accounts (pp. 426–471), literature cited (pp. 473–493), an appendix giving for each species treated in the book the list of West African countries where it occurs (pp. 495–499), and an index to currently used scientific names (pp. 501–503).

The geographical introduction offers useful maps and 41 excellent photos of various biotopes found throughout the region covered, all with precise locality data. The biotope photo for Guinea-Bissau (page 17) shows in its foreground an intriguing roundish object, which actually is a *Chelonia mydas* (Linnaeus, 1758), and the locality is more precisely Poilao Island (J.-F. Trape, pers. comm., Aug. 2012).

The introduction to the herpetofauna treated provides excellent drawings to illustrate scale nomenclature. On the lizard head scale drawing (p. 27), the number corresponding to the subocular scale is missing. This chapter also presents recent taxonomic changes and brings important new ones, that we should briefly mention here since they might be overlooked by non-French speaking readers. These include the revival from synonymy of *Agama africana* (Hallowell, 1844), *A. boensis* Monard, 1940 and *A. insularis* Chabanaud, 1918 (the latter already revalidated by Trape 2011) (Agamidae), of *Mochlus mocquardi* (Chabanaud, 1917), *Trachylepis aureogularis* (Müller, 1885) and *T. keroanensis* (Chabanaud, 1921) (the latter actually already revalidated by Böhme et al. 2011) (Scincidae), the elevation to species rank of *Trachylepis paucisquamis* (Hoogmoed, 1978) (Scincidae) and of *Tarentola hoggarensis* Werner, 1937 and *T. senegambiae* Joger, 1984 (Gekkonidae), the synonymization of *Agama sylvanus* Macdonald, 1981 with *A. africana* (Agamidae), of *Philochortus lhotei* Angel, 1936 with *P. zolii* Scortecci, 1934 (Lacertidae), of *Mabuia guineensis* Monard, 1940 with *Trachylepis perroteti* (Duméril & Bibron, 1839), and of *Panaspis nimbensis* (Angel, 1944) with *P. tristaoi* (Monard, 1940) (Scincidae). Most importantly, nine new lizard taxa are described within this chapter (with different authors as indicated): *Uromastyx dispar hodhensis* J.-F. Trape & S. Trape *in* J.-F. Trape, S. Trape & Chirio, 2012 (Agamidae), *Hemidactylus albituberculatus* J.-F. Trape *in* J.-F. Trape, S. Trape & Chirio, 2012, *H. albivertebralis* J.-F. Trape & Böhme *in* J.-F. Trape, S. Trape & Chirio, 2012, *H. kundaensis* Chirio & J.-F. Trape *in* J.-F. Trape, S. Trape & Chirio, 2012, *Tarentola pastoria* J.-F. Trape, Baldé & Ineich *in* J.-F. Trape, S. Trape & Chirio, 2012 (Gekkonidae), *Acanthodactylus boskianus nigeriensis* J.-F Trape, Chirio & Geniez *in* J.-F. Trape, S. Trape & Chirio, 2012 and *A. b. khattensis* J.-F. Trape & S. Trape *in* J.-F. Trape, S. Trape & Chirio, 2012 (Lacertidae), *Cophoscincopus senegalensis* S. Trape, Mediannikov & J.-F. Trape *in* J.-F. Trape, S. Trape & Chirio, 2012, and *Leptosiaphos dungeri* J.-F Trape *in* J.-F. Trape, S. Trape & Chirio, 2012 (Scincidae). There is no mention of the sex of the holotype and the paratype of *Uromastyx dispar hodhensis*, of the holotype of *Hemidactylus albituberculatus, H. albivertebralis* and *H. kundaensis*, of the holotype and paratypes of *Tarentola pastoria, Leptosiaphos dungeri, Cophoscincus senegalensis, Acanthodactylus boskianus nigeriensis* and *A. b. khattensis*. This is very unfortunate, but is a deliberate choice made by J.-F. Trape who did not want to dissect and damage the types to verify their sex (J.-F. Trape, pers. comm., Oct. 2012). The descriptions of *Uromastyx dispar hodhensis, Cophoscincopus senegalensis* and of both new subspecies of *Acanthodactylus* are accompanied by phylogenetic trees, but there are no details on methodology and no museum numbers indicated for the comparative specimens used. *Hemidactylus albituberculatus* is said to differ from *H. angulatus* only by a slightly larger size, more colorful and contrasted dorsal tubercles and by genetics, but no data on genetics are provided; obviously a better characterization of this species will be needed, including the actual results of the genetic analysis. The diagnosis of *Acanthodactylus boskianus nigeriensis* (relatively small size, females and juvenile without bright colors on tail) is insufficient to help identify specimens of this population.

At most five days before the present book appeared, two agamid species were co-described by two of its co-authors: *Agama parafricana* J.-F. Trape, Mediannikov & S. Trape *in* Mediannikov, S. Trape & J.-F. Trape, 2012 and *A. wagneri* J.-F. Trape, Mediannikov & S. Trape *in* Mediannikov, S. Trape & J.-F. Trape, 2012 (Mediannikov et al. 2012). The latter paper was published in a volume that appeared on June 25th, 2012 according to the website of the Russian Journal of Herpetology, while the date shown on the book is June 2012, which has to be interpretated as June 30 at the latest.

The list of species provided at the end of this chapter shows that, among the 179 species and subspecies treated in the book (156 lizards, 3 crocodiles and 20 turtles), 23, i.e., 13%, were described in the 21st Century. Among them, relatively large and colorful geckos such as *Hemidactylus beninensis* Bauer, Tchibozo, Pauwels & Lenglet, 2006, a terrapin *Pelusios cupulatta* Bour & Maran, 2003, and the gecko *Pristurus adrarensis* Geniez & Arnold, 2006 which represent a 4,700 km range extension for the genus (Geniez and Arnold 2006); all this indicates that much remains to be discovered in this part of the world.

Identification keys are abundantly illustrated. Some of them unfortunately include mistakes. In the key to Agamidae, page 69, there is no link to couplet 22; actually the second alternative from couplet 19 should be 22, not 23 (J.-F. Trape, pers. comm., Oct. 2012). In couplet 21, re. *Agama sankaranica* Chabanaud, 1918, the variation given for the number of scales on the vertebral line is different from the variation given in the species account (31–46 versus 31–39). In couplet 28, re. *Agama parafricana*, the variation given for the number of scales on the vertebral line is different from the variation given in the species account (29–34 versus 29–37), and the same is true for the midbody scale rows (54–72 versus 54–63). In the Gekkonidae key, the caption of the photo of *Hemidactylus richardsoni* on p. 81 wrongly indicates that it was taken in "Ivindo, Gabon" – for having taken the photo ourselves (OSGP), we know that it was actually taken in Gamba, southwestern Gabon (idem with both photos of the same individual p. 243). In couplet 22, it is indicated that *Hemidactylus albivertebralis* has a "paravertebral" whitish stripe – it is actually a vertebral stripe. In couplet 30, re. the *Tarentola mauritanica* complex, the variation given for the number of lamellae under the 5th toe (16–20) differs from the one given in the species account (16–21), giving the impression that there is no overlap with the key's alternative species *T. deserti* Boulenger, 1891 (21–25). In couplet 34 (p. 89), re. *Tarentola senegambiae* Joger, 1984, the variation given for the number of granular scales between the eyes (14–18) differs from that provided in the species account (13–17). In the Lacertidae key, page 95, there is no link to couplet 20; actually the second alternative from couplet 12 should be 20, not 21 (J.-F. Trape, pers. comm., Oct. 2012). In couplet 20 (p. 98), 10 to 14 ventral scale rows leads to couplet 21, which, however, itself leads, among others, to *Acanthodactylus dumerilii* (Milne-Edwards, 1829) whose range for this

character is said to be 12 to 16 in its species account. In the same couplet 20, one reads that *A. longipes* Boulenger, 1921 shows 60–77 dorsal scale rows at midbody, whereas the corresponding species account says the species has 55–88. In the key to Scincidae, page 105, there is no link to couplet 23; the second alternative from couplet 19 should in fact be 23, not 22 (J.-F. Trape, pers. comm., Oct. 2012). In couplet 21, re. *Cophoscincus greeri* Böhme, Schmitz & Ziegler, 2000, the key indicates 48–57 paravertebral scales *contra* 45–57 in the species account. In couplet 25 p. 107, the variation in the number of keels on the paravertebral row in *Mochlus brevicaudis* (Greer, Grandison & Barbault, 1985) is indicated as 8–15 *contra* 7–15 in its species account, which means an overlap with the variation for the alternative species in the key. We found other discrepancies between variation given in some keys and variation given in associated species accounts, but contrary to the ones cited above, they do not impact the use of these keys.

Species accounts include clear and well-written sections on rapid diagnosis, size, geographic distribution and habitat, description and natural history, and are each illustrated by a distribution map (with squares of 1 × 1 degrees, in red when the species has been recorded within the square) and two photos. It is a pity that there is no distinction in geographical distribution between literature data and new data added by the authors, as the new data certainly represent a large part of the known distribution for many species.

The iconography of the book is absolutely exceptional. The photos, all in colour, are of outstanding quality. Among the *ca.* 650 reptile photos shown (besides the numerous scale drawings and biotope photos), 567 (thus about 87%) were taken by the authors. Only a single species, *Trapelus schmitzi* Wagner & Böhme, 2007 (Agamidae) could not be illustrated alive. All photos are accompanied by precise locality data, which adds much informative value to the book, and the vast majority of the photos were taken within the geographical area covered by the book. Taking some of the photos was a real challenge; for example taking those of *Acanthodactylus boskianus* (Daudin, 1802) in Galtat Zemmour (p. 295) or trying —unsuccessfully—to take some of *Uromastyx occidentalis* Mateo, Geniez, López-Jurado & Bons, 1998 at its type locality required crossing mine fields (J.-F. Trape, pers. comm., Oct. 2012). On page 303, in the species account for *Acanthodactylus busacki* Salvador, 1982, both photos illustrate the same individual, although two distinct localities are indicated; the actual locality for both photos is "surroundings of Tan-Tan, Marocco" (J.-F. Trape, pers. comm., Oct. 2012).

When we (OSGP) asked the first author why *Hemidactylus ansorgii* Boulenger, 1901 was indicated as occurring from Guinea to Gabon (p. 224), while the species is unknown in the latter country (Pauwels and Vande weghe 2008), he indicated to us that Gabon was actually a *lapsus calami* for Cameroon (J.-F. Trape, pers. comm., Oct. 2012). Regarding that species, let us mention that its common name "Ansorg's Half-toed Gecko" as mentioned by Trape et al. is erroneous, the species having been dedicated to the explorer William John Ansorge (1850–1913, see Beolens et al. 2011).

The literature cited includes 502 references. There are remarkably few typographical errors in the book. We warmly recommend the purchase of this excellent opus which represents a nice addition to any natural history library because of its beautiful photos, showing many species that have rarely or never been illustrated alive before. But, above all, this book deals with a fauna that was never synoptically treated before, and represents a major milestone in the progress of African herpetology.

Acknowledgments.—We are grateful to Jean-François Trape (Institut de Recherche pour le Développement, Dakar, Senegal) and Laurent Chirio (Grasse, France) for providing useful information.

The increasingly rapid pace of discovery and description of new taxa, along with the taxonomic revision of long-known groups, has made an accurate accounting of regional herpetofaunal diversity difficult for even the most dedicated specialists to track. Recent years have seen a remarkable proliferation of quality reference books dealing with the rich Mesoamerican herpetofauna, that is, those amphibians and reptiles occurring east of the Isthmus of Tehuantepec and southward through Panama. Given the large number of species known from this region, most works are necessarily limited to a single country or protected area, with few books attempting to deal large segments of the entire regional herpetofauna (Wilson

et al. 2010). One notable exception has been Gunther Köhler's *Reptiles of Central America* (2003, 2008), which managed to combine comprehensive taxonomic coverage with extensive illustrations and identification keys to provide the best approximation of a regional field guide ever published. That invaluable reference has now been joined by an equally well-produced companion volume, Köhler's *Amphibians of Central America*.

Like its companion, *Amphibians of Central America* is small enough (17 × 23.5 cm) to be carried into the field, at least as well as other available "field guides" that claims coverage beyond a single protected area. The book boasts 930 color photographs that include nearly 90% of the 498 species covered within, along with 177 maps and 92 other illustrations, all contained in 379 pages that feel relatively svelte in the hand. Following a four page foreword by Larry David Wilson, the book begins with an Introduction chapter that immediately alludes to both the "breathtaking" diversity of Mesoamerican amphibians, as well as the dramatic declines in wild populations of many taxa witnessed by the author as well as the majority of other researchers that have worked in Central America over the past 25 years. It is within this dual context that the import of this reference comes into focus.

The Introduction includes a section entitled "Comments on the Usage of this Book," which includes details of the conventions for using the dichotomous keys and the structure of each taxonomic section. Species-rich groups such as *Bolitoglossa* and Terrarana each have two identification keys, one for northern and for southern geographic regions divided at the Nicaraguan Depression. The Introduction is followed by a two-page illustrated "Classification of the Amphibians of Central America," which shows the genera and number of constituent species from each of the 16 regional families.

A chapter entitled "The Environment" provides general descriptions of major habitat types found in Central America, along with representative photographs from five of the eight countries covered in the book. These habitats are grouped into "Rainforest," "Cloud forest," "Dry forest," and "Marshes, swamps, and seasonal flooded forest," which somewhat undersells the region's rather remarkable ecophysiographic diversity, but adequately details the habitats for the purposes of the book. This chapter also includes two full page, full color maps; one illustrating topography and the other showing vegetation zones. Finally, the chapter includes the section "Climate in Central America," with climate diagrams showing mean daily and nightly temperature and monthly precipitation throughout the year for nine localities in eight countries. These nine localities represent a spectrum of elevational ranges on both Caribbean and Pacific versants, and one Caribbean island (Utila, Honduras).

After these introductory sections, the bulk of the book consists of the taxonomic accounts covering the breadth of the Central American amphibian fauna, beginning with a one page summary of the Class Amphibia and a key to the three orders of amphibians. This is followed by the nine page section on caecilians, which also introduces the format for subsequent sections. The section starts with a rather detailed two page introduction to the Order Gymnophiona, including aspects of the group's biology, ecology, and distribution from a global perspective. A photograph and two illustrations depict the critical morphological characteristics used in the identification keys, which are relatively few, given the simplified body plan of caecilians. Only a single family is represented in Central America, the Caeciliidae, and, as is the case with all family-level accounts, a key to the constituent genera and a list of additional references is provided. The rest of the section is divided into accounts for each of the four genera present in Central America: *Caecilia*, *Dermophis*, *Gymnopis*, and *Oscaecilia*.

These generic accounts, along with the rest of those in the book, follow the now familiar format seen in both editions of *Reptiles of Central America*, making usage of the new companion volume almost second nature for those accustomed to using the *Reptiles* book. Each account contains one or more paragraphs that provide a general introduction to the genus, which includes details if its taxonomic content, distribution, natural history, and recent research, with content varying based on the information available for each genus. Each generic account then contains a list of the Central American species, with information on their original description (author, citation, and type locality) and a summary of their known distribution. Information about species are set apart in pale yellow text boxes, making visual identification simple. Each generic account is rounded out with one or more maps showing the known distributions of species, a key to the species of the genus, and a list of further references specific to the group.

The generic accounts for the caecilians are well illustrated, considering the relatively poorly-known nature of many species compared with their salamander and anuran relatives. Three of four species of *Caecilia*, three of six *Dermophis*, both species of *Gymnopis* and the three species of *Oscaecilia* are represented by color photographs of live animals, with four species represented by two photographs each.

The 57-page section dealing with the salamanders covers eight genera (not seven, as stated on p. 36) and 151 species within the single family Plethodontidae. The key to the eight genera of Central American plethodontids is accompanied by illustrations showing the external diagnostic characteristics and roof of the mouth of a generalized plethodontid, as well as photographs of the dorsal and ventral aspects of the foot of *Bolitoglossa heiroreias*, a species possessing distinct toes and subdigital pads. With the majority of plethodontid diversity contained within the genera *Bolitoglossa* and *Pseudoeurycea*, it is not surprising that the generic account for the primarily Central American *Bolitoglossa* encompasses some 30 pages (only six species of *Pseudoeurycea* occur east of the Isthmus of Tehuantepec, with most of its diversity found to the west and north in Mexico).

Nearly one-third of the pages in the *Bolitoglossa* account are taken up by color photographs, generally of live animals and of good quality. Only a single species is represented by a photograph of a preserved specimen (*B. pygmaea*), and I detected one case of a misidentified photograph (Fig. 59: labeled as *B. dunni*; this photo is representative of a male *B. diaphora* from the same locality). The identification key for *Bolitoglossa* is necessarily (and thankfully!) divided into two parts: one for southern Mexico to Nicaragua, and a second for Nicaragua to Panama. The author has taken the welcome step of providing photographs of the dorsal surfaces of the feet of 48 species of *Bolitoglossa* to accompany the keys, a useful and stylish touch. This attention to detail becomes a welcome thematic element in all the identification keys presented in *Amphibians of Central America*. The taxonomic content of this section was also apparently kept updated right up until publication; for example, a number of recently described Guatemalan species (Campbell et al. 2010) are represented not only in the keys and generic accounts but also by color photographs.

With many fewer species to deal with, the accounts for other plethodontid genera are much shorter, but nonetheless maintain

the author's commitment to providing color photographs of as many species as possible, including uncommonly illustrated taxa from genera such as *Dendrotriton* and *Nototriton*. The identification keys for *Cryptotriton*, *Dendrotriton*, and *Nototriton* all contain close-up photographs of the lateral aspects of the heads of most constituent species, which should further aid in identification of these small and difficult to distinguish salamanders. The generic account for the more diverse *Oedipina* (29 species) is equally well-illustrated, and the keys are supplemented with dorsal head photographs of five species and dorsal views of the hind feet of four species.

Naturally, the taxonomic accounts for the Class Anura make up the bulk of *Amphibians of Central America*, with 205 pages covering 14 families and 332 species, accompanied by another 16 pages dealing specifically with tadpole identification. Without exception, each family and genus receives the same excellent treatment as was apparent in the preceding sections. The key to the anuran families of Central America is accompanied by six illustrations and five color photographs meant to show specific characteristics used in the keys, with more detailed illustrative figures reserved for family and generic accounts, an approach that does a good job of balancing the informative and utilitarian aspects of the book. Perusing the expansive anuran section of the book, with extensive photographic coverage of the majority of species, gives the reader an opportunity to visually appreciate the remarkable amphibian diversity of Central America like few other references afford.

Taxonomically, families such as Bufonidae, Centrolenidae, Dendrobatidae, and Ranidae follow recent revisionary generic arrangements, rather using than traditional mega-genera such as *Bufo* and *Rana*. Within the Bufonidae, for example, the genera *Atelophryniscus*, *Atelopus*, *Chaunus*, *Crepidophryne*, *Incilius*, *Rhaebo*, and *Rhinella* are recognized. In cases where the recognition of particular taxa may be a matter of some controversy in the literature (such as the genus *Atelophryniscus* and species *Incilius ibarrai* and *I. porteri* within Bufonidae), the author clearly states his justification for usage on a case by case basis, usually within the descriptive narrative that makes up the initial portion of a given generic account.

While the extensive use of color photographs are a major strong point of *Amphibians of Central America*, it is, in this reviewer's opinion, the illustrated keys that stand out as exceptional. As anyone who has attempted to construct dichotomous keys for large numbers of taxa will attest, undertaking the development of keys that are both accurate and easy to use can be an enormous challenge. Doing so for speciose groups as notoriously difficult to identify as *Craugastor*, *Diasporus*, or *Pristimantis* could be considered an almost herculean task, yet Köhler manages to combine these, along with the remaining genera of Central America Terrarana (New World direct-developing frogs), into two workable, geographically-delimited keys. The two identification keys for Terrarana encompass some 18 pages, and, like all other keys in the book, are extensively illustrated with photographs and drawings that clearly demonstrate key diagnostic characteristics. Only extensive application of these keys in field and laboratory settings will reveal any hidden flaws, but admittedly my attempts to challenge the accuracy of the keys in identifying relatively challenging specimens of *Craugastor* from my own Honduran collections were unsuccessful; that is, the keys worked in each test case.

The illustrations and keys in the account for Hylidae may be the most visually impressive in the book, owing both to the natural beauty of many species in this family as well as to the extensive selection of diagnostic drawings and photographs used in the keys, at the family level as well as in the generic accounts. Few opportunities to show comparative photographs or illustration of hands are foregone when showing differences in the condition of the prepollex or nuptial pads are referenced in an associated key. Likewise, few instances of species not represented by a color photograph in life are apparent; in fact, I found myself actively searching for such cases just to see how many I could uncover, and came to the conclusion that the effort was not worthwhile given that it amounts to such a relatively minor shortcoming in such an otherwise comprehensive treatment.

The last part of the Anura section deals specifically with the identification of anuran larvae. This section begins with an overview of tadpole morphology an ecology, and details of terminology used in tadpole identification. The written descriptions of the morphological terminology are augmented by two diagnostic illustrations showing key characteristics of tadpole body plans and the oral disk and mouthparts. A table listing 41 species of Central American anurans whose larvae lack published descriptions is provided. An identification key to tadpoles for over 150 species follows, taking some 14 pages to present what may be one of the better illustrated key of its kind ever produced. The same attention to detail shown in the other keys presented in the book is evident in the tadpole key, with macro photographs of mouthparts and dorsal and lateral aspects of bodies throughout.

Any work focused on Mesoamerican amphibians would be remiss if the subject of regional amphibian declines was not discussed, and the author presents an 11 page chapter dealing with this subject as an epilogue to the taxonomic guide. This section presents a concise summary of factors leading to declines, including those familiar culprits such as habitat degradation and chytridiomycosis. Also discussed are the potential impacts of global climate change, ultraviolet-B exposure, and parasite infestations. A summary of recent "rediscoveries" of Central American anurans previously feared extinct is presented, followed by a discussion on potential approaches to mitigating the loss of amphibian diversity in the region and beyond. A final page discusses the use of amphibians as biological indicators, with the author concluding that "there is no evidence to indicate amphibians are better bioindicators than other animals," and that amphibian declines or extirpations do not in themselves indicate the potential loss of other biodiversity elements.

As a herpetologist working in Central America, this book becomes an instant "must-have" resource, and for the foreseeable future will have place on the nearest bookshelf to my desk as well as secured within a plastic bag in my *mochila* on fieldtrips to Mesoamerica. While the list price for this book is regrettably high (a seemingly unavoidable circumstance in the modern climate of scientific book publishing), there are few references available that provide such a comprehensive treatment of a regional fauna in such a manageably-sized package. The author's attention to detail and commitment to Neotropical herpetology are admirable, and *Amphibians of Central America* stands not only as an irreplaceable resource for regional biologists, but as a broadly accessible catalog of a declining endemic fauna of global conservation priority. Perhaps the most commendable aspect of this book is the skill with which Köhler has been able to construct a guide which is both valuable to specialists and visually striking and accessible to non-specialists, and my hope is that this book will provide further impetus for uniting the former and the latter in the name of protecting the remarkable amphibian fauna of Central America.

The latest contribution devoted to the study of the Balkan Peninsula in the Edition Chimaira series is volume 35 of the Frankfurt Contributions to Natural History: *Die Amphibien und Reptilien Bulgariens*, authored by Andrei Stojanov, Nikolay Tzankov, and Borislav Naumov. The book is a synthesis of accumulated research spanning well over a century, interpreted within a modern scientific framework that covers diverse branches of biology such as systematics, taxonomy, ecology, ethology, paleobiology, and biogeography.

By European standards, this mid-sized country harbors an impressive diversity comprising 58 widely accepted species. This variety is largely due to Bulgaria being on the crossroads between the Orient and continental Europe and exhibiting diverse climate and topography, resulting in a melting pot containing European, Pannonian, Balkan, Mediterranean, and Oriental faunal elements and integrades thereof.

Interest in the Bulgarian herpetofauna has long been overshadowed internationally by that of its neighboring countries of Greece and former Yugoslavia, largely due to historic political reasons. Regrettably, dedicated research on the herpetofauna of Bulgaria has been a source of neglect domestically as well. This was caused partially by lack of support from the government for the development of herpetological institutions and the resulting limited employment opportunities, producing few local professionals. Additionally, much of the collected information has been published in journals in Bulgarian, severely restricting the accessibility of the results to foreign researchers and thus hindering successful international collaborations.

As a result, comprehensive scientific catalogues and guides on the Bulgarian herpetofauna have been few and far between. Some, such as the seminal works from mid-20th century by Ivan Buresch and Jordan Zonkow, became obsolete or were aimed specifically at professionals (Beškov and Beron 1964) or at the general public (Beshkov and Nanev 2002). As a result, the accumulation of knowledge on the distribution, biology, and ecology of the Bulgarian herpetofauna has been inadequate, although such information is currently needed as never before in the face of the global declines of amphibians and reptiles.

Fortunately, herpetological research in Bulgaria has been revived with a recently emerged generation of highly competent herpetologists who have established a productive collaboration. The three authors of the book under review form an essential part of this trend. They have well over 50 years of field experience combined, and are based at the National Museum of Natural History-Sofia and the Institute of Biodiversity and Ecosystem Research. Their collective effort is manifested in the production of this present work; over five years have been dedicated specifically to the production of its 592 pages (A. Stojanov, pers. comm.), a volume which exceeds by over two and a half times the latest similar work by Biserkov (2007).

Our first impressions of the book are the sheer amount of information, presented on high quality paper, enveloped by a sturdy cover. The layout of the pages is highly professional and the typography is easy on the eyes and allows for a smooth, comfortable reading experience. For example, separator lines at the header and figures smoothly align across the pages with very few exceptions (e.g., pp. 136–137).

The volume is extensively illustrated and includes 614 high quality maps, photos, and sketches. Most of the photos have been contributed by the authors themselves and were chosen to be included in the book after an extensive comparison, to provide the best available photographic material: spectacular scenery, depiction of amphibian species of different stages in their life cycles, behaviors such as mating, dorsal and ventral aspects of lizards, etc. Most of the pictures have been taken specifically for this book, usually by means of a high-end analog camera utilizing slides (A. Stojanov, pers. comm.). Sadly, a few images suffer from minor chromatic aberrations likely to have arisen during the scanning processes, doing the original material little justice.

Overall, the book content is divided into three major sections: an introduction, detailed species accounts, and an extensive bibliography. Following a preamble by the publisher and the acknowledgements is a short user guide presenting the way the species accounts are constructed and interpreting the maps and associated data. A list of well-chosen, intuitive and easy to use abbreviations is also included.

To make the book useful for a general readership, the authors provide general remarks on the geopolitical and biogeographical features of the territory of the Bulgarian Republic by supplementing maps of major landmarks, geographical,

climatic and biogeographical features. In addition, this section of the book includes a succinct, but well-illustrated description of the major habitats with dominant and typical vegetation and animal species, putting the herpetofauna into a broader biological context. A table defining the chorotypes of the species is also provided (pp. 37–38). These features of the book are especially useful for readers who are unfamiliar with the geography and fauna of the country and are eager to rapidly obtain general information.

A brief history of herpetological research in Bulgaria is presented. This information is later followed by detailed systematic and taxonomic remarks. Of great value is the table on p. 72 summarizing the information on taxonomic changes in the Bulgarian herpetofauna from the early 20th century until the present-day.

The last segment of the section is devoted to the past and current conservation of Bulgarian amphibians and reptiles. It contains a full description of the current conservation status of each species in the most important international and local lists such as the IUCN Red list, CITES, and Bulgarian legislation. Brief information is presented on current administration and legislation in the country relating to nature conservation, as well as contact information for some of the major entities devoted to the study and protection of the herpetofauna.

The species account section stands out as the greatest asset of the book. For each family, a synopsis of about one page presents general information for the taxon. After that brief introduction, highly detailed and accurate information for each species is presented on 2–4 pages with description and remarks on its biology, ecology, behavior, reproductive biology, geographic range, chorotype and conservation status; the species accounts are elegantly woven into a succinct format, with data compiled from a vast swathe of seminal works, obscure printed sources, and personal observations. To facilitate accurate determination, specific characteristics differentiating each species are presented along with identification keys in tables. The description of the species follows a rigorous and well-chosen format, which allows information to be found quickly and conveniently. For every species the authors include Latin, German, English, and Bulgarian names (the last in Cyrillic with a transcription). A useful feature that provides a realistic perception of the species' approximate size is the use of graphic outlines in different colors for the average- and maximum size of adult individuals, juxtaposed to a human hand or legs in a stride; in addition, a centimeter ruler is given alongside. For each species, multiple photos are provided (up to 17 per species), carefully selected to deliver a well-rounded depiction of the species, demonstrating intraspecific variability, life stages, colorations, dimorphism traits, specific behaviors and key identification features.

Furthermore, the geographic range of each species is illustrated on separate maps. The inclusion of thousands of the authors' personal records from locations rarely if ever visited previously by herpetologists (N. Tzankov, pers. comm.), combined with all available literature records and multiple data contributed by colleagues, is among the strengths of the book. The distribution of subspecies and contact zones is displayed using legends of contrasting colors (for example the map for the Common Wall Lizard *Podarcis muralis*, p. 383). Potential locations where the species is likely to be found in the future are also noted with a "?". In contrast to previous works, the range is superimposed onto a detailed map including relief and major rivers, thereby defining each location precisely and allowing the reader to study the distribution in greater detail.

An innovative and useful feature is the inclusion of simple graphical representations beside each map of the local optimal and suboptimal altitudinal distribution of the species, and temporal information on its seasonal and reproductive activity, including mating, egg deposition (if any), and metamorphosis or hatching.

The venomous snakes (Adder *Vipera berus*, Nose-horned Viper *V. ammodytes*, Eastern Montpellier Snake *Malpolon insignitus*, and Cat Snake *Telescopus fallax*), are given special consideration in a separate section due to the multiple misconceptions and misunderstandings surrounding these animals. In addition to a clear and objective overview that addresses the topic, general advice is provided for responding in cases of envenomation. The applicability of the instructions has proven its worth in two unintentional field misfortunes involving vipers, to which one of the authors of this review (YVK) was a witness. Although stressful and unpleasant for all participants, these situations did not result in long term harm to anybody, but demonstrated the highly undeserved notoriety of vipers.

The book also provides updated information on unresolved and controversial issues such as the historic records of Asp Viper *Vipera aspis*, Meadow Viper *V. ursinii*, and the few observations of vagrant individuals of Green Turtle *Chelonia mydas* and Loggerhead turtle *Caretta caretta*.

In a separate section, the authors describe in comparable detail six extraterritorial species that are either probably present at the moment but have not yet been unambiguously detected, or that have high chances of extending their range into Bulgaria. These include three water frogs, two lizards, and a viperid snake. The last species account section is committed to describing the single introduced species in Bulgaria—the Red-eared Slider, *Trachemys scripta elegans*, which is currently believed to be reproducing in the wild and poses significant conservation challenges. Altogether, the total number of species described in the book is 64.

The species accounts are followed by the bibliographical section—an exhaustive compilation totaling 489 references, including some old, rare, obscure, and elusive sources. The added advantage is the duplex citation format of Romanized and Cyrillic script ensuring facilitated literature search, since no unilaterally standardized transliteration format for Cyrillic exists. This ease of use greatly extends the value of the bibliography and allows readers to easily look for additional sources if interested. Regrettably, this section suffers from minor typesetting and typographical errors, but that does not detract from the usefulness of the accumulated information.

The reference list is followed by a glossary, which covers the most essential terminology. This is followed by the inclusion of a transliteration/pronunciation guide, a strength of the book to aid non-native speakers; we have tried it with foreign friends and colleagues and obtained positive results.

Overall, the high quality of this book is unequalled in its field and marks a milestone in the history of Bulgarian herpetology. The authors have faced a gargantuan task in compiling years of personal field experience along with that of their colleagues and tracking down a vast array of literature, resulting in an unprecedented richness of data brilliantly condensed into this volume. For any researcher involved in the study of the herpetofauna of the Balkan Peninsula or for the interested naturalist *Die Amphibien und Reptilien Bulgariens* should constitute an essential part of their library and is bound to become a standard reference for many years to come.

e-mail: uncshai@post.tau.ac.il

This book is a mixture of two main themes: an update on the herpetology of Pakistan in general, and a detailed account of the results of a seven year survey by the author of the herpetofauna of a single national park near Islamabad, the Margalla Hills National Park. The book, which is organized in a field-guide format, starts with a brief introduction to the geography and biogeography of Pakistan, and the ways and degrees to which some regions are being designated for conservation. This is followed by a list of national parks, and maps depicting the topography and hydrography of Pakistan, as well as major districts (but not, strangely, the boundaries of the national parks). The area at the focus of the book, namely the Margalla Hills National Park, is then described in some detail. The introduction finishes by moving back to all of Pakistan, providing a list of herpetological works carried out there and, importantly, mentioning poorly studied regions. A short "Methodology" section provides a general description of the methods the author used in his survey of the Margalla Hills National Park.

The main section of the book begins with a checklist (Chapter 1) and key (Chapter 2) to the 42 species of reptiles and amphibians of the Margalla Hills National Park. Chapters 3–6 occupy the majority of the book, providing information on the amphibians, turtles, lizards and snakes of the park. Species descriptions comprise the following sections: Diagnostic Features, Description, Habits and Habitat, (global) Distribution, and (for some species only) Remarks, which can include information on conservation, behavior, geographic variation, or other topics.

The species descriptions are usually good but brief, and to an extent, inconsistent. For example, the usually very detailed morphological description is followed by no body size estimate for some species (e.g., *Calotes versicolor*). Furthermore, size estimates are probably too low for adult *Cyrtopodion scabrum*, and minimum size is probably reported as maximum size for *Asymmblepharus himalayanus*. Likewise, data on sexual size dimorphism are only reported for some species (including some that other works show are dimorphic). There is usually a fairly detailed description of behavior and phenology – but only sometimes of reproductive biology, life history, diet, temperature, etc. (e.g., no breeding data are provided for a well-known species such as *Varanus bengalensis*). The pictures of the species are good, if a little small. The maps depict the distribution throughout Pakistan (based on Minton 1966, Khan 2006, and specimens from the Pakistan Museum of Natural History) and are clear and precise. However, perhaps rather than political maps, physical maps, or maps of biogeographic regions/ecoregions would have been more helpful.

The book ends with a table (Chapter 7) of distribution of the species by habitat, and a discussion of conservation threats (Chapter 8), followed by a glossary, a bibliography, and a checklist of all the 210 species of reptiles and amphibians inhabiting Pakistan. In a recent review of this book Vyas (2012) commented on what he perceived as doubtful distribution data for Pakistan (e.g., species that are found on border regions in India, but are missing from the adjacent part of Pakistan according to Masroor). Vyas (2012) further pointed to a few taxonomic issues, and corrected some of the distribution data Masroor listed for India in his book. He further listed seven species that were included in the Pakistani species list by Minton (1966) and Khan (2006), but are omitted from the list in the current work.

Khan's (2006) book, dealing with all the amphibians and reptiles of Pakistan, is worth mentioning here, because one might wonder, as I have, whether there is a place for a book on Pakistani reptiles and amphibians, six years after the publication of that work. Masroor's (2012) book certainly has some advantages. It is more up to date in its data and taxonomy, has better maps (more precise and providing more data, although the Indus and its tributaries are marked in Khan's book, but not in Masroor's) and more detailed data. It is certainly smaller and lighter than the large format book of Khan (2006), and would thus make a much better field companion. This brevity, however, may also be its main problem, as it may have little appeal to a wide audience, focusing on just one 174 km^2 national park. While the data in the book are valuable, its narrow scope may deter potential users, who may be more interested in the Pakistani fauna as a whole.

Peril in the Ponds: Deformed Frogs, Politics, and a Biologist's Quest

by Judy Helgen. 2012. University of Massachusetts Press (www.umass.edu/umpress). 243 pp. Softcover. US $24.95. ISBN 978-1-55849-946-1.

MICHAEL J. LANNOO

e-mail: mlannoo@iupui.edu

Combat veterans, reflecting back on their lives decades later, often realize that they never felt more alive than when they were in action, surrounded by death. You get the same sense of this from Judy Helgen as she describes in *Peril in the Ponds* what it was like to be at ground zero when, in the mid-1990s, a local malformed frog problem got big fast, and exploded into the global malformed frog phenomenon. By this time, Helgen, in her 50s, had already raised a family and was a successful soft-money employee with the Minnesota Pollution Control Agency (MPCA), a state government unit that, based on its battles with 3M, had a reputation for being scrappy and persistent.

In the interest of full disclosure, I was a part of this story. I first met Judy Helgen and her MPCA colleague Mark Gernes before there were malformed frogs to discuss—in 1993, in Jamestown, North Dakota, at a Wetlands Symposium hosted by biologists at the USGS's Northern Prairie Science Center. We had dinner and talked about amphibians as aquatic bioindicators. A couple years later, when the malformed frog phenomenon began, Helgen and I talked more frequently. As the investigation proceeded, I was mostly in the background (Dave Hoppe and Bob McKinnell, in the University of Minnesota system, were in the field; biologists at the National Wildlife Health Center in Madison were doing necropsies and making diagnoses). Mid-investigation, I recommended that Helgen bring on the classically trained parasitologist, Dan Sutherland, who was then on the faculty in the University of Wisconsin system. I also radiographed MPCA-collected frogs. In 2001, Sutherland, his student Josh Kapfer, and I re-sampled the hottest of the Minnesota hotspots. Having been a part of Helgen's story, I can assure readers that she tells the truth. She does not play herself up, and when she calls out folks it's for things they actually did; no straw men populate Helgen's stories.

Helgen discovered in the late 1990s what many others have so painfully learned—that you will not find instructions anywhere on how to proceed when day-to-day reality blows up and metastasizes into uncertainty and malevolence. Dogged by cameras and microphones, politicians, bosses, and scientists, Helgen and Gernes sought to discover what was causing the apparent epidemic of malformed frogs across much of Minnesota, and—true to the MPCA mission—determine whether or not humans, especially the school kids who first found those funny looking frogs, were in harm's way. Helgen describes how National Institutes of Environmental Health Science (NIEHS) scientists came onboard and immediately found themselves in competition for answers with Environmental Protection Agency (EPA) scientists. Her MPCA bosses were bipolar—sometimes supportive, more often distanced—she rarely knew where she stood within her agency, a big concern for a soft-money employee. Willard Munger, the legendary progressive politician, was consistently supportive; so was Bob McKinnell, the biologist who pioneered the idea (from studying leopard frogs) that viruses can cause cancer. Dave Hoppe was a steady, stabilizing presence in the field, as was Dan Sutherland, who helped separate parasite fact from fiction.

Helgen faced many problems, including: the need for immediate answers to unanswerable questions (should the State deliver bottled water to families deemed in harm's way?); the pressure of the press; the need to build a team of scientists; the need to simultaneously collect data and discuss results at state and national forums; competition among federal government agencies; smokescreens set by distant scientists with a deep need to be the center of attention; and the simple biological fact, as we now know, that there was more than one cause for the malformations that were being observed.

Perhaps the most fundamental problem Helgen faced was that the MPCA had no contingency plans for what might happen should an environmental concern blow up into an emergency (or public relations nightmare). The U.S. Forest Service, for example, having lost several smokejumpers by placing them in the wrong place at the wrong time, developed an Incident Command Structure (ICS). This model provides a mechanism for populating a disaster response team that includes adding administrative overhead appropriate to the task. (Imagine an organization as a pyramid, with bosses on top. An ICS model adds personnel to one side, including more experienced people, recognizing that a fire boss capable of handling a 10-acre fire may not be capable of handling the same fire after it blows up to 10,000-acres). Because MPCA (despite the implications of the name "pollution control") never adopted anything like an ICS contingency plan, once Helgen initially took charge of the malformed frog investigation, she became, de facto, always in charge of the malformed frog investigation. When she needed assistance, MPCA added a layer to the base of the organizational pyramid (i.e., technicians—less experienced people). Under such a system, no one in her position could have possibly succeeded; the fact Helgen did so well is a credit to her and her primary team.

While the political difficulties Helgen describes with her agency—being a state entity in a region dominated by agriculture—are predictable, the political difficulties created by a handful of then-respected scientists are deeply disturbing. As Helgen notes, there is nothing quite like a catastrophe to bring out the best and the worst in people. And, whether we acknowledge it or not, among our fellow scientists there are a lot of ambulance chasers looking for ways to fund their labs or get their names in the papers. Helgen treats most of these folks with kindness, or not at all (many were transient; my favorite was a USDA biologist who claimed to have found a new life form at the CWB site). However, Helgen does not hold back when it comes to her feelings for proponents of the parasite theory—the idea that amphibian malformations are caused by tissue disruption during

development by metacercarial cysts of the trematode *Ribeiroia ondatrae* (Rib). It's not that the parasite theory was wrong; the problem was that it could not—despite the deepest wishes of its loudest proponents—be generalized to all hotspots. People were confusing "a" cause for malformed frogs with "the" cause for malformed frogs. The parasite theory for frog malformations was always the best story, but as Helgen points out, in Minnesota it was never the best science.

A short elaboration from someone who was there. As a field biologist, imagine that you have a set of observations where you see a clear pattern "X," but that someone half a continent away who has never seen your study sites or your animals is telling both you and the press that it is pattern "Y." That's the way the parasite hypothesis played out in Minnesota. First the facts: using data assembled by Dan Sutherland, we found every possible combination of Rib/malformation hotspot interaction (Rib/hotspot; Rib/no hotspot; no Rib/hotspot; no Rib/no hotspot). We then concluded that the distribution of Rib and the distribution of hotspots were independent. Where Rib and hotspots co-occurred, Rib was the likely cause of malformations. However, one big and simple factor worked against Rib as a general explanation for frog malformations: in hotspots where Rib did not occur, Rib could not have been the cause (Lannoo et al. 2002).

But the parasite hypothesis is beautiful, and paraphrasing Thomas Henry Huxley, none of us really enjoys destroying beautiful hypotheses with nasty, ugly little facts. Helgen describes how the parasite hypothesis was transformed from idea—something that grows and expands a discipline—to ideology—something that constrains and dictates. With contrary data in hand, we reminded ourselves of Aldo Leopold's observation that the fundamental weakness of conservation biology is that many of its proponents, although unaware of it, come to value personal prestige over real conservation (Meine 1988). We were also reminded of the marine biologist W. K. Fisher, who, as Ed Ricketts described, had too much integrity to fit for convenience what wouldn't fit in fact (Rodger 2006). One clear pattern that did emerge from our field observations, something Helgen notes, was that most malformed frog hotspots were either wetlands recently constructed or highly altered (usually through runoff which could contain nutrients and/or contaminants). These oddball wetlands disproportionately produced Minnesota's oddball frogs.

Helgen's book completes a trilogy of volumes on the Minnesota's malformed frog phenomenon. The first was Bill Souder's *A Plague of Frogs* (Souder 2000), which covered the investigation from a reporter's perspective—from all angles while looking for answers. The second was my own *Malformed Frogs* (Lannoo 2008), which laid out the science of amphibian malformations and put global and historical perspectives on the Minnesota issue. Helgen's new book is by far the most personal, but they all tell the same story—that had we spent the same amount of money differently and considered each site independently, we would have likely solved the malformed frog phenomenon. And that much of the trouble was that the special needs or wants of people and agencies got in the way and added complexities that were expensive to consider and impossible to overcome. *Peril in the Ponds* will make a major contribution to the field of investigative science if, during the next environmental train wreck, some smart, mid-level professional who finds themself in the middle of either a scientific or public relations meltdown, says: "This will not be another punching Judy show; what happened to Helgen in Minnesota will not happen to us. Let's set up an organization with clear lines of responsibility and accountability, then assemble the resources to get the job done." It's a strategy that may not (given human foibles) always work, but as combat veterans also know, the way through a minefield is often laid out by those who went before and didn't make it.

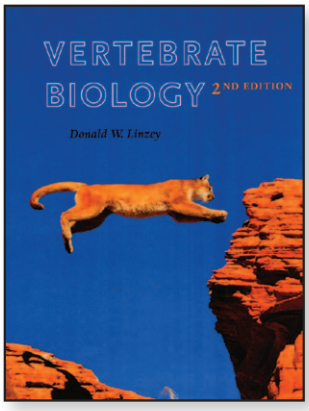
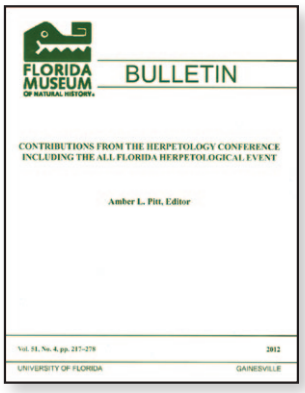
PUBLICATIONS RECEIVED



Rainbow Boas—Natural History & Captive Husbandry

by Henry Bellosa and Hans Bisplinghof. 2012. Edition Chimaira, Frankfurt am Main, Germany (www.chimaira.de). 223 pp. Hardcover. € 39.80 (approx. US $51.50. ISBN 978-3-89973-494-2.

This is an English translation of the German-language title *Regenbogenboas Das Kompendium*, also issued in 2012, devoted to *Epicrates cenchria* and *E. maurus*, beautifully iridescent snakes of Central and South America that are also very popular subjects for herpetoculturists. The book is organized into chapters concerning systematics, distribution and habitat, subspecies, captive breeding, husbandry requirements, diseases and parasites (authored by Frank Mutschmann), and color and pattern morphs (authored by John R. Berry). A glossary and list of references are included, but there is no index. Although "natural history" is part of the book's title, the focus is unmistakably on life in the terrarium. Aside from habitat photos from various parts of the range, new information concerning ecology and natural history is lacking. Three subspecies of the more northerly occurring *E. maurus* are recognized, while the widely distributed *E. cenchria* is described as having eight poorly defined subspecies, though clearly with extensive phenotypic diversity. The book is lavishly illustrated, with excellent photographs of snakes and their habitats, maps, illustrations, and diagrams—nearly all in color.

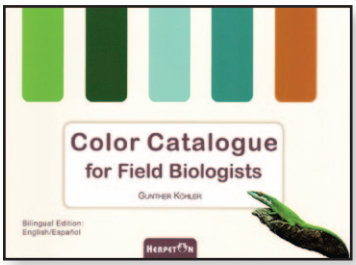


Vertebrate Biology, 2nd edition

by Donald W. Linzey. 2012. The Johns Hopkins University Press (www.press.jhu.edu). Hardcover. xi, [4], 583 pp. US $110.00. ISBN 978-1-4214-0040-2.

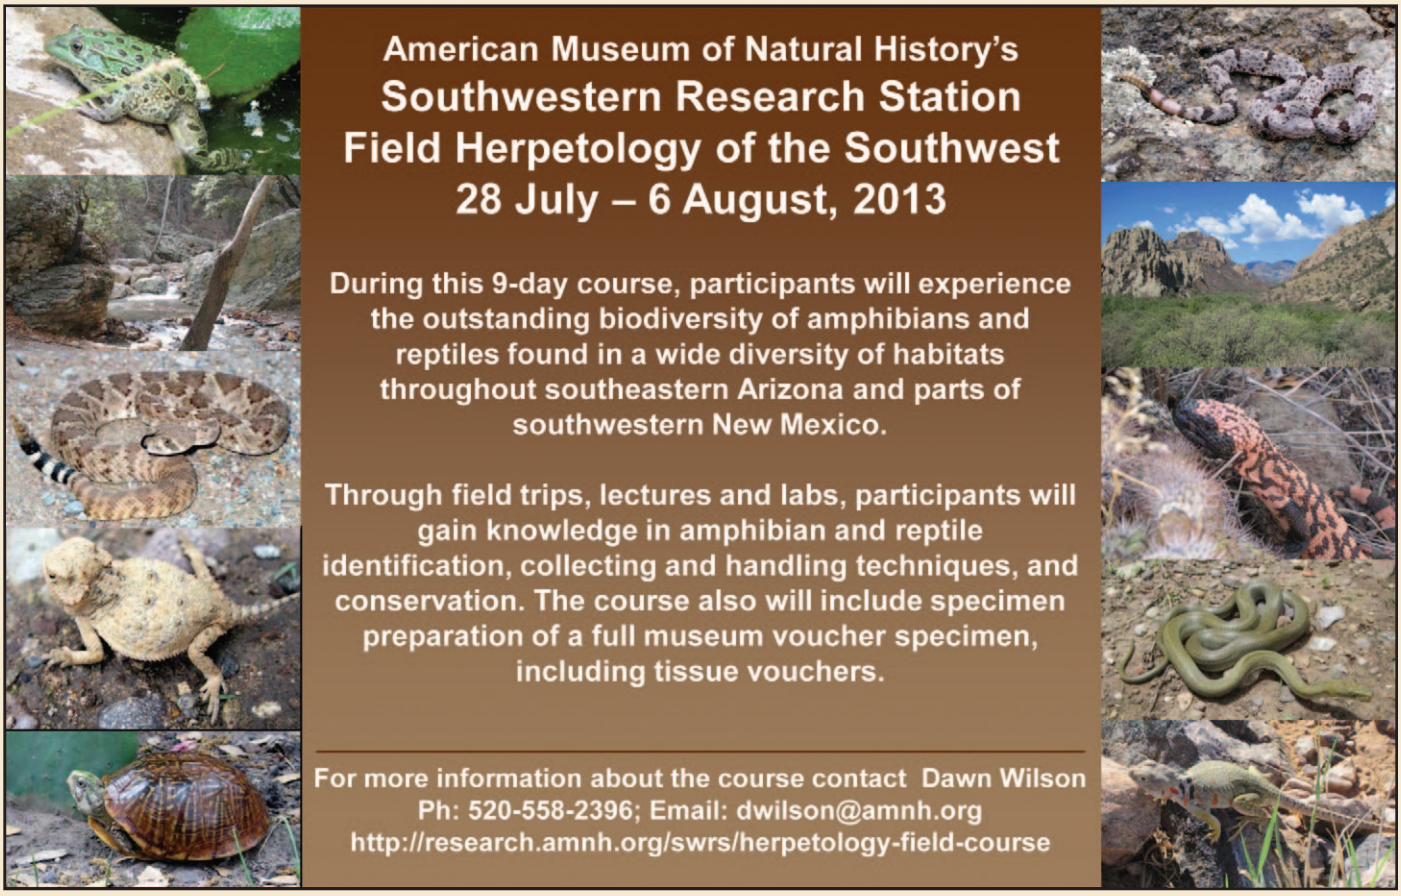
This is a vertebrate biology textbook covering the evolution, form, function, and ecology of all of the major chordate lineages. In addition, zoogeography, extinction, and conservation are also dealt with. Evolution, morphology, reproduction, growth and development are treated group by group (e.g., gnathostome fishes, amphibians, reptiles including birds, etc.), whereas other topics (population dynamics, movements, intraspecific and interspecific ecology and behavior, extinction and extirpation, and conservation and management) are dealt with in chapters that discuss all vertebrate groups. An atypical, but useful chapter for such a book is "Techniques for Ecological and Behavioral Studies." Each of the book's 16 chapters concludes with review questions and topics, supplemental reading, and a list of relevant internet sites. The last of these is critical for any modern class in vertebrate biology, but must be diligently revised over time to remain current. Together the amphibian and reptile chapters occupy 137 pages of text (closer to 100 if avian reptiles are excluded). Appendices provide a classification of vertebrates (to order for fishes and family for tetrapods) and a list of endangered vertebrates in the United States, and there is an extensive glossary, a bibliography of more than 1600 references, and a subject index. The volume is illustrated throughout by black and white photos, diagrams, maps, and graphs. The formal classification is largely up-to-date with respect to recent higher order taxonomic changes and most herpetological information is current, but there are a few errors (e.g., the turtle hyoplastron is labeled as the hypoplastron, p. 204; the name *Alligator lucius*, a very old synonym of *A. mississippiensis*, is used in a figure, p. 224; an egg-eating *Dasypeltis* is identified as *Elaphe obsoleta quadrivittata*, p. 213) and some topics, such as turtle phylogeny, are out of date. At $110.00 the book is priced about the same as competing texts and at 482 pages of actual text it presents a concise overview of vertebrate biology, appropriate for a single semester course on the topic.

Contributions from the Herpetology Conference Including the All Florida Herpetological Event



edited by Amber L. Pitt. 2012. Bulletin of the Florida State Museum of Natural History Vol. 51, No. 4, pp. 217–278.

This is a special volume of the *Bulletin of the Florida State Museum of Natural History* containing five separate papers from the Herpetology Conference including the All Florida Herpetological Event, a meeting that has been hosted in Gainesville for several decades. The first such volume of its kind, its included contributions are diverse, but four are directly relevant to the southeastern quadrant of the United States. These include Hecht-Kardasz et al. on "Population structure of the hellbender (*Cryptobranchus alleganiensis*) in a Great Smoky Mountains stream," Johnston et al. on "Population ecology of the snapping turtle (*Chelydra serpentina osceola*) in a northern Florida river," Nickerson et al. on "Historical turtle population decline and community changes in an Ozark River," and Mohr on "Movements of



the timber rattlesnake (*Crotalus horridus*) in the South Carolina mountains." The fifth contribution is by Byram and Nickerson on "Effects of nitrogen ammonia and MS-222 on *Xenopus laevis* development, growth, and foraging behavior." Appropriately, the volume is dedicated to Max Nickerson, long the driving force behind the conference, who is also an author on three of the included papers. The publication has the standard format of the *Bulletin* and the papers are illustrated in black and white with numerous graphs and maps. The *Bulletin* has a long history of herpetological publications, both neontological and paleontological, which are available for hard copy purchase or free download (see www.flmnh.ufl.edu/bulletin/bulletin_vols.htm and http://ufdcweb1.uflib.ufl.edu/ufdc/?a=ufirg&m=hitflmnh).

Color Catalogue for Field Biologists

by Gunther Köhler. 2012. Herpeton Verlag Elke Köhler, Offenbach, Germany (www.herpeton-verlag.de). Softcover. 49 pp. Euro 24,80 (approximately US$ 32.70). ISBN 9783936180404.

This dual language (English/Spanish) book serves the important function of providing field biologists with the tools to accurately describe the coloration of animals, particularly in life. Although many authors invest little effort in their descriptions of color, some biologists have strived to use a standard terminology to make their color descriptions as useful as possible. For many years the standard reference work in this field was the *Naturalist's Color Guide* by Frank B. Smithe, which provided 182 color swatches to which organismal colors could be matched. This volume replaces the now out-of-print Smithe and adds additional colors for a total of 300. The bulk of the oblong, spiral-bound book is made up of 30 pages of color swatches (10 per page), including approximations of the familiar colors from Smithe with names adopted accordingly. The book also gives definitions for terms used in color description, such as suffusion, splotches, chevrons, and bands. A series of 24 color photos of mostly Neotropical amphibians and reptiles (four to a page) illustrate the use of these terms and three detailed examples of color descriptions are also provided. Although herpetological examples are used, any biologist who needs to accurately describe color could make good use of the *Color Catalogue*. Reference to this book (or to another color guide, such as that of Smithe) should be considered as a "best practice" for species descriptions and other publications for which color documentation is important.

INFORMATION FOR CONTRIBUTORS

Herpetological Review is a peer-reviewed quarterly that publishes, in English, articles and notes concerning the study of amphibians and reptiles, as well as book reviews, commentaries, regional and international herpetological society news, and letters from readers directed to the field of herpetology. Articles reporting the results of experimental research, descriptions of new taxa, or taxonomic revisions are not published in ***HR***, but should be submitted to the ***Journal of Herpetology*** (for information, please refer to: http://www.ssarherps.org/pages/JHinstr.php). To submit a manuscript to ***HR***, please consult the SSAR webpage at:

<http://www.ssarherps.org/pages/HRinfo.php>

REPRINTS AND PAGE PROOFS

Page proofs are sent electronically to authors of all articles, book reviews, and obituaries, but are not prepared for natural history, geographic distribution, or herpetoculture notes. Proofs are sent as pdf files approximately 2–4 weeks prior to publication. High resolution electronic (pdf) reprints of notes, articles, book reviews, and obituaries are provided at no charge to the primary/corresponding author as a benefit of SSAR membership. Reprint files will normally be sent prior to the issue mailing date from the printer. Authors who are not current SSAR members may purchase pdf reprints from the SSAR Publications Office.

ADVERTISING

Herpetological Review accepts commercial advertising. Rates and copy information are available from the SSAR web page (http://www.ssarherps.org/pages/HRinfo.php).

Herpetological Review (ISSN: 0018-084X) is published quarterly (March, June, September, and December) by the Society for the Study of Amphibians and Reptiles at Central Michigan University, Department of Biology, 217 Brooks Hall, Mt. Pleasant, MI 48859, USA. Periodicals postage paid at Mt. Pleasant, MI 48859 and at additional mailing offices.

All rights reserved. No part of this periodical may be reproduced without written permission of the Editor, except that authors and their agents are permitted to reproduce and distribute their own articles and notes.

POSTMASTER: Send address changes to Breck Bartholomew, SSAR Publications Secretary, P.O. Box 58517, Salt Lake City, UT 84158. **MISSING OR DAMAGED ISSUE?** Please notify Breck Bartholomew, SSAR Publications Secretary (e-mail: ssar@herplit.com) for a replacement.

SSAR PUBLICATIONS

SSAR publishes seven different series: *Journal of Herpetology, Herpetological Review, Facsimile Reprints in Herpetology, Contributions to Herpetology, Herpetological Circulars, Herpetological Conservation*, and the *Catalogue of American Amphibians and Reptiles* (see below for CAAR details). SSAR members receive prepublication discounts on all *Facsimiles* and *Circulars* and on volumes in the *Contributions* and *Herpetological Conservation* series. A complete pricelist of Society publications is available at: http://www.ssarbooks.com/.

CATALOGUE OF AMERICAN AMPHIBIANS AND REPTILES

The ***Catalogue*** consists of loose-leaf accounts of taxa prepared by specialists, including synonymy, definition, description, distribution map, and comprehensive list of literature for each taxon. Covers amphibians and reptiles of the entire Western Hemisphere. Available for purchase from the SSAR Bookstore (http://www.ssarbooks.com/). Use the prices below to order back issues.

COMPLETE SET: NUMBERS 1–880	check website below for current pricing
INDEX TO ACCOUNTS 1–400: Cross-referenced, 64 pages	$6
INDEX TO ACCOUNTS 401–600: Cross-referenced, 32 pages	$6
SYSTEMATIC TABS (Ten tabs to fit binder: "Class Amphibia," "Order Caudata," etc.)	$6
IMPRINTED POST BINDER (Note: one binder holds about 200 accounts)	$35
INCOMPLETE SET: NUMBERS 1–190	$75
191–410	$85
411–840	$320

To order: make checks payable to "SSAR" and mail to Breck Bartholomew, SSAR Publications Secretary, P.O. Box 58517, Salt Lake City, Utah 84158, USA (fax 801/453-0489). e-mail: ssar@herplit.com. Online orders at: http://www.ssarbooks.com/.

POINTS OF VIEW

Best Practices: In the 21st Century, Taxonomic Decisions in Herpetology are Acceptable Only When Supported by a Body of Evidence and Published via Peer-Review
H. KAISER, B. I. CROTHER, C. M. R. KELLY, L. LUISELLI, M. O'SHEA, H. OTA, P. PASSOS, W. D. SCHLEIP, W. WÜSTER 8

Anecdote vs. Substantiated Fact: The Problem of Unverified Reports in the Toxinological and Herpetological Literature Describing Non-front-fanged Colubroid ("Colubrid") Snakebites
S. A. WEINSTEIN, J. WHITE, A. WESTERSTRÖM, D. A. WARRELL 23

ARTICLES

Population Genetic Structure and Revised Geographic Range for the Tridactyl Skink (*Brachymeles muntingkamay*) from Luzon Island, Philippines
C. D. SILER, L. J. WELTON, A. A. ROCK, R. M. BROWN 30

The Dog-faced Water Snake (*Cerberus rynchops*) and Gerard's Mud Snake (*Gerarda prevostiana*) at the Western Edge of Their Distribution
R. V. VYAS, J. C. MURPHY, H. K. VORIS 34

Morphological and Molecular Variation in the Endemic and Poorly Known Honduran Jumping Pitviper *Atropoides indomitus* (Serpentes: Viperidae), with Notes on Distribution
J. R. McCRANIE, L. V. ORELLANA , C. M. SHEEHY III 37

Applied Anatomy of the Eyelash Viper (*Bothriechis schlegelii*)
E. O. CLARKE, III, R. PATTANARANGSAN, M. K. STOSKOPF 40

Hoop Net Escapes and Influence of Traps Containing Turtles on Texas Spiny Softshell (*Apalone spinifera emoryi*) Captures
I. MALI, D. J. BROWN, M. C. JONES, M. R. J. FORSTNER 44

Relationships of Body Size and Male Melanism to Biting Propensity in Red-eared Sliders (*Trachemys scripta*)
R. HITES, G. CADDELL, M. E. B. STONE, P. A. STONE 46

Body Size and Sex Ratio in a Population of Spotted Turtles (*Clemmys guttata*) in Southwestern Michigan
J. W. ROWE, J. R. GRADEL 49

Reproductive Behavior of *Anotheca spinosa* (Anura: Hylidae) Under Natural Conditions in Costa Rica
S. RODRÍGUEZ-BRENES, B. HILJE, C. SÁNCHEZ 54

Spectral Analysis Reveals Limited Potential for Enhanced-Wavelength Detection of Invasive Snakes
S. R. SIERS, G. A. SWAYZE, S. P. MACKESSY 56

TECHNIQUES

Use of an Infrared Thermographic Camera to Measure Field Body Temperatures of Small Lacertid Lizards
S. LUNA, E. FONT 59

Modification of Camera Traps for the Study of Ectothermic Vertebrates
M. MERCHANT, Z. LI, J. SULLIVAN, A. COOPER 62

A Method for Telemetry-based Logging of Animal Activity
B. LARDNER, J. A. SAVIDGE, R. N. REED, G. H. RODDA 65

Working with a Full Deck: the Use of Picture Cards in Herpetological Surveys of Timor-Leste
M. O'SHEA, H. KAISER 68

A Comparison of Two Methods to Assess Territorial Aggression in the Lizard *Uta stansburiana*
M. L. ANDERSON, L. A. WHITE, S. F. FOX 76

Applicability of "Tablet" Computers for Use by Field Biologists
R. A. SEIGEL 82

HERPETOCULTURE

Observations on the Endangered Iranian Zanjan Viper, *Montivipera albicornuta* (Squamata: Viperidae), in Captivity and in the Wild
N. KIAN, M. KABOLI, M. KARAMI, J. B. MURPHY 86

Larval Growth and the Potential for Head-starting of Eastern and Ozark Hellbenders (*Cryptobranchus alleganiensis alleganiensis* and *C. a. bishopi*)
S. D. UNGER, A. MATHIS 89

AMPHIBIAN DISEASES

Batrachochytrium dendrobatidis in Amphibians of the Piedmont and Blue Ridge Provinces in Northern Georgia, USA
R. HUANG, L. A. WILSON 95

Batrachochytrium dendrobatidis Not Detected in Anurans in the Northern Kimberley Region of Western Australia
D. J. McLELLAND, I. SMITH, L. OLDS, C. MYERS, L. F. SKERRATT 98

SOCIETY FOR THE STUDY OF AMPHIBIANS AND REPTILES

www.ssarherps.org

The Society for the Study of Amphibians and Reptiles, the largest international herpetological society, is a not-for-profit organization established to advance research, conservation, and education concerning amphibians and reptiles. Founded in 1958, SSAR is widely recognized today as having the most diverse society-sponsored program of services and publications for herpetologists. Membership is open to anyone with an interest in herpetology—professionals and serious amateurs alike—who wish to join with us to advance the goals of the Society.

All members of the SSAR are entitled to vote by mail ballot for Society officers, which allows overseas members to participate in determining the Society's activities; also, many international members attend the annual meetings and serve on editorial boards and committees.

All members and institutions receive the Society's primary technical publication, the *Journal of Herpetology*, and its bulletin, *Herpetological Review*; both are published four times per year. Members also receive pre-publication discounts on other Society publications, which are advertised in *Herpetological Review*.

To join SSAR or to renew your membership, please visit the secure online ZenScientist website via this link:
http://www.ssarherps.org/pages/membership.php

Future Annual Meetings
2013 — Albuquerque, New Mexico, 10–15 July (JMIH with ASIH, HL, and AES)
2014 — Chattanooga, Tennessee, 30 July–3 August (JMIH with ASIH, HL, and AES)
2015 — Lawrence, Kansas, dates 30 July - 3 August

THE IMPORTANCE OF EARNEST OUTREACH: SSAR AND BEYOND

"Public understanding of science not only affects people's ability to appreciate and make full use of the products of science, it also contributes to the extent of support for scientific research. Yet far too many scientists are reluctant to engage with people outside their own community."
Alan I. Leshner, CEO American Association for the Advancement of Science (2012 Science 337:777)

It is hard to believe that my two-year term as President of SSAR is coming to an end this month. While being president of a major society was never a specific goal of mine, contributing to herpetology on behalf of the animals we study has been a lifelong goal. I will use this piece to continue with the theme I visited in my last essay: the importance of broadening all aspects of SSAR in order to better serve the different stakeholders within the herpetological community and, moreover, to best serve the needs of the animals upon which we base our hobbies and careers. In the past few years, I have given many lectures in a range of venues, from universities to zoos to herp clubs to nature centers to cub scouts. I have noticed that many of our colleagues and members are doing some really amazing work in the realm of what people generally refer to as public education or outreach. I would like to highlight some of their efforts here.

The current widespread popularity of reptiles and amphibians as pets, and the omnipresence of these animals in documentaries and television wildlife programs, is inconceivable to many of us because they were summarily ignored—or worse—by most of society and public media until relatively recently. In the USA, where I was raised, Raymond Ditmars was arguably the first important public proponent in the early 20th Century for the wonder of reptiles and amphibians. Mid-century saw zoo collections improve their standards of care (Petzold 2008. *The Lives of Captive Reptiles*. Contributions to Herpetology 22. SSAR, Ithaca, New York. 275 pp.) and the development of programs and educational materials for the public by people like Bill Haast, Robert Stebbins, Doris Cochran, Carl Kauffeld, Roger Conant, Archie Carr, and Ross Allen. More recently, colleagues like Marty Crump, Rafael Joglar, Joe Collins, Kate Jackson, Harry Greene, Mike Lannoo, and Luis Coloma, among others, have produced academically sound books and programs aimed toward the general public. While great nature programming on television existed, produced by people like Marlin Perkins or Jacques Cousteau, it very rarely included any non-menacing or non-sensational coverage of herps except perhaps for the occasional chelonian.

The pet trade was limited, entirely based on wild-caught animals, and was so specialized and out of the view of the public that it rather resembled the illegal black market trade of today. So it is very heartening today to see a pet trade that includes so many captive-bred animals, even if over-collection and other unacceptable problems related to commercial trade persist. Regional societies, such as the Chicago Herpetological Society, host enormously popular annual reptile and amphibian shows where the animals are showcased, not sold. It is encouraging to see zoos, aquariums, nature centers, and botanical gardens stepping up to be leaders in reptile and amphibian research and conservation, over and above their more traditional roles as educators and public attractions.

Similarly, while natural history museums have traditionally been leaders in research, conservation is becoming more important in their programs as well; AmphibiaWeb, based out of the Museum of Vertebrate Zoology at University of California Berkeley is as much about conservation as it is about biodiversity. Herpetological eco-tour program are now available, through organizations such as Green Tracks (www.greentracks.com) or the Costa Rican Amphibian Research Center (www.crarc.com); eco-tours traditionally have focused mainly on birds or marine mammals.

There even has been progress in the horrific realm of rattlesnake roundups, as only three U.S. states (shamefully!) still permit them. In 2012, the event in Claxton, Georgia, voluntarily transformed itself from a "roundup" into a "festival" of rattlesnakes. No snakes were killed there, nor likely ever will be again, and the local community attracted a record-breaking attendance.

In recent years, many regional herpetological societies have focused on pets and husbandry, but more and more, groups in places like Chicago, Dallas-Fort Worth, and Kansas are stacking their speaker rosters with research- or conservation-oriented herpetologists. Most states or regions now have detailed field guides available, such as the exemplary *"Field Guide to Amphibians and Reptiles of the San Diego Region"* by Jeff Lemm (University of California Press, Berkeley, 344 pp.). Reptiles and amphibians also are featured nearly exclusively on a number of well-produced educational programs hosted by colleagues like Brady Barr or Jeff Corwin, even if a few unfortunately exploitative or overly sensational programs still seem all too prevalent. Importantly, I often see my colleagues having their research or conservation programs featured on wildlife programs and nightly news broadcasts. How delightful it is to see media coverage on a great piece of herpetological work and to think "Hey, I know that person!" Indeed academics are getting better at attracting and engaging the media. Related to this point, I highly recommend the book *Escape from the Ivory Tower: A Guide to Making Your Science Matter* (Nancy Baron, 2010. Island Press) to educate oneself on the realities of dealing with media communications as a scientist.

In a recent essay (2012. *Herpetological Review* 43[2]:165–166) I emphasized the importance and value of citizen science to inform academic herpetology. Now it is time to make sure academics are giving something back to a public that is primed and eager to learn about these animals and their conservation challenges. The SSAR membership includes a wonderfully engaging group of people ranging from hobbyists to undergraduates to emeritus academic faculty or curators who have much to offer to the public and, therefore, much

to offer to the animals we study. Outreach education is how public perceptions are changed; the near demise of rattlesnake roundups is evidence of this. Some of our members contribute a lot already, but I challenge all of us to consider reaching out to a nature center, community group, K–12 school, library, or similar venue to give a fun talk about herpetology or your research. Perhaps lead your own eco-tour to a local wetland. Invite non-traditional people to assist at your study site; Gad Perry does this all the time (Gerbert 2012. IRCF Reptiles & Amphibians 18:110–115). Honestly, some of the most interesting insights I have had to my own research have germinated from naïve (not "dumb" mind you!) questions from a public audience. SSAR does a good amount of outreach already. In 2010 SSAR set up a booth at the first annual National Science Fair on the National Mall in Washington, DC (2010. *Herpetological Review* 41[4]:409–410). The event was attended by over a million members of the public and I was proud to see virtually all of the "big-name" herpetologists in the DC area tirelessly working the booth all day long. I am also proud to point out that the SSAR Roger Conant Grants-in-Herpetology program that Josh Kapfer leads has always had a funding category specifically dedicated for herpetological education. Finally, I will highlight a few exceptional outreach education programs, among others too numerous to mention here, that I have encountered in the last couple of years.

Education and celebration of wildlife has long been central missions of zoos and natural history museums, but while reptiles and amphibians have always been exhibited, they were never a focus in any positive sense. I encourage everyone to go back and read about the extraordinary program "Toad Trackers" that Rachel Rommel (2012. *Herpetological Review* 43[2]:417–421) created at the Houston Zoo; this program turns every participating kid into a contributing citizen herpetologist! Who says that herps can't party? Jennifer Stabile, while she was at Central Florida Zoo, created a massively popular *Festival del Coqui,* wherein proud Puerto Ricans and their international friends converge for a few days of frenzied frog-focused partying and learning about the "other" coqui species native to their island (proyectocoqui.org; centralfloridazoo.org). Zoo associations across the world recently have developed successful programs to raise awareness and, importantly, conservation funds with campaigns such "Year of the Frog" and "Shellshock" for amphibians and chelonians, respectively, in recent years.

In the realm of the Ivory Tower, we were all proud in recent years to watch Whit Gibbons, Bob Powell, and Mike Dorcas receive the Meritorious Teaching Award in Herpetology co-sponsored by SSAR, ASIH, and HL. I believe a large part of the reason these three people earned the award is because each of them stepped up and implemented educational programs that go far outside their typical academic job descriptions. Whit is a tireless proponent of public lectures; I think he has given as many such lectures in the Atlanta area as I have in the last eight years, and he does not even live in this city. Bob, with his energetic and innovative approach to field courses, has single-handedly turned many dozens of undergraduates into peer-reviewed published herpetologists and produced more than a few career academics. Mike's lab also churns out high quality undergraduate publications, but he further empowers his undergraduates to lead a very busy schedule of public outreach events and maintain a website (http://www.bio.davidson.edu/people/midorcas/outreach/Outreach.htm) that is more informative for North Carolina citizens than is typical of most state or national parks. Similarly, John Maerz (University of Georgia; http://ugaherpsociety.uga.edu/Home.html) and Kraig Adler (Cornell University; http://www.rso.cornell.edu/cuherps/) among others, selflessly volunteer as faculty advisors for campus herpetology clubs that inspire undergraduates as well as connect with thousands of members of the public. I am pretty sure that these extra-curricular efforts do not figure strongly in their annual evaluation for promotion and tenure.

There are many more great campus and zoo programs, public proponents and educators, and popular media outlets for herpetology than I can include here. As I mentioned, I am simply pointing out a subset with whom I have had the pleasure of visiting lately and with a clear bias toward programs in my native country. My main point is that every SSAR member owes it to society and our favorite animals to devote some time and energy toward outreach education in any sense or framework that fits your position and expertise.

As I end my term as President of SSAR, I am so very proud to have represented a hard-working membership and team of chairpersons, officers, board members, and editors who have made a difference in modern herpetology—and the public perception of the discipline and the animals involved. SSAR has put a lot of energy in recent years to ensure that it remains relevant to the ever-changing roles of research, conservation, and education in our corner of the biological sciences. We have done so much in terms of new and revamped programs to try to make SSAR more inclusive and accessible and relevant for the broadest membership possible. We have decreased membership rates for certain groups of stakeholders. We have expanded our concept of "student" to truly mean *all students* of any age. We have increased and expanded our awards and grants programs for students. We have a new mentorship program to make sure first-timers at annual meetings feel oriented and welcomed. We have revamped *Journal of Herpetology* and *Herpetological Review* to accomplish what seemed impossible: make them more colorful, more attractive to new readers, retained top-quality content, yet are less expensive to publish and ship. As user expectations have evolved, we have made two of our signature publications series (*Herpetological Review* and *Catalogue of the American Amphibians and Reptiles*) now available as downloads and searchable electronically for the first time ever. We have waived all page-charges for members to publish in our journals. We remain committed to publishing works that are of primary importance for understudied areas of the world (Masroor 2012. *Contribution to the Herpetology of Northern Pakistan*. SSAR Contributions to Herpetology. 217 pp.), newly emerging fields of study (Mitchell et al. [eds.] 2008. *Urban Herpetology*. Herpetological Conservation 3. SSAR, Salt Lake City, Utah. 586 pp.), truly affordable facsimile reprints of classical volumes of incalculable importance (*Erpétologie Génerale, by* Duméil and Bibron, published by SSAR November 2012; see *Herpetological Review* 43[3]:362), and that cross-inform stakeholders in agencies, the public, and academia (Crother 2012. Scientific and Standard English Names of Amphibians and Reptiles of North America North of Mexico, with Comments Regarding Confidence in our Understanding. SSAR Herpetol. Circ. 39. 92 pp.). We allocated funds to make our website a most vital herpetological portal; we are working on this now.

But how do we measure success as a taxon-based society? *Journal of Herpetology* was recently ranked among "Top 100 Journals in Biology and Medicine in the Past 100 years" by the Special Libraries Association. I would point to the fact that both *Journal of Herpetology* and *Herpetological Review* have represented more nations than ever before, both in terms of study sites and—more importantly—nationalities of authors. I would also point to the amazing fact that SSAR appears to be one of the only taxon-based professional societies in biology that is not suffering a precipitous decline in membership. Declines in taxon-based societies are a regrettable modern reality, and certainly not an opportunity to gloat. However, self-reflection is appropriate at this time. What I have tried to describe in my series of informal "Presidential Essays" is the reality of being a taxon-based

biologist in a modern age. Harry Greene famously defended the importance of natural history (1993. *Herpetological Natural History* 1:3). Natural history is the study of all aspects of nature by all interested persons. I believe that SSAR can attribute its survivorship and relative success to its breadth of publications, its non-arrogant open-door policy for contributors, and a membership that invites, and appreciates, well beyond the Ivory Tower. Speaking personally, I have spent my entire life hoping to contribute to herpetology. My CV might suggest that I have done so, but my term as President of this vital society has convinced me that I have done so. Thank you, to the entire SSAR membership for all that we do.

Acknowlegments.—Rachel Rommel, Jen Stabile, Jessica Tingle, Nitya Rao, John Archer, Danny Beckwith, Cyndi Carter, Carl Franklin, and Bob Hansen provided essential information and conversations for this essay. Harry Greene, Jenny Pramuk, Karen Lips, George Rabb, Jim Murphy, Beth Timpe, Mike Dorcas, Bob Johnson, Mike Lannoo, Andy Odum, Ron Gagliardo, Danny Benboe, Kristine Kaiser, Sean Graham, Brad Lock, Robert Hill, Luke Wyrwich, Stacy Graison, David Brothers, Jason Brock, Bob Hansen, and many others have joined-shared many relevant discussions with me over the years.

Joseph R. Mendelson III
President

ABOUT OUR COVER: *Strophurus taenicauda*

The family Diplodactylidae contains about 120 species of geckos endemic to the Australian region. They occur throughout the continent with outliers in New Zealand and New Caledonia. The 17 species of *Strophurus* are among the more unusual members of this diverse family.

Strophurus occur in dry to arid areas of Australia. They have broad padded digits and tend to climb among slender objects, grasping twigs, thin branches, and grasses. The species fall broadly into arboreal and tussock-inhabiting groups. The jewelled and striped geckos (*S. elderi*, *S. jeanae*, and their allies) dwell exclusively in grasses and sedges. Most inhabit the interlocking matrix of tough spines that form hummocks of *Triodia*, a genus of drought-resistant grasses dominating the arid landscape. Tussock-inhabiting *Strophurus* have dotted or simple linear patterns. Arboreal species, including spiny-tailed geckos (*S. ciliaris* and its relatives) shelter under the bark of dead saplings, in narrow hollows and among foliage. Some of these species are distinctively ornamented with rows of spines along the tail and sometimes over their eyes.

Strophurus share an extraordinary defensive strategy. The ability to expel sticky repellent fluid from glands set deep within the tail appears unique to *Strophurus* and the New Caledonian genus *Eurydactylodes*. The substance can be dribbled and smeared, or a fine jet may be forcibly ejected up to half a meter. The fluid initially has a treacle-like consistency, drying quickly to cobweb-like filaments. It is not known to be toxic (Richardson and Hinchliffe 1983. Copeia 1983[1]:161–169) but when experimentally applied to mealworms they were distasteful to chickens (Rosenberg and Russell 1980. Can J. Zool. 58:865–881). It can certainly cause eye irritation in humans, resulting in redness and discomfort that may persist for several hours.

The substance may be metabolically expensive to produce, as the geckos seem reluctant to expel it except under extreme circumstances. They rarely squirt fluid when captured by hand but will do so if handled roughly or grasped by a predator. There can be little doubt that a face-full of sticky irritant fluid would give a small predator cause to reconsider its options.

Unlike other Australian geckos, *Strophurus* exhibit some diurnal tendencies. While not actively foraging by day, the lizards can often be encountered basking in direct or dappled sunlight. *Strophurus williamsii* has been recorded clinging fully exposed to a wire fence in temperatures exceeding 40°C. The lizard had adopted pale, heat-reflecting hues and did not appear remotely stressed by the temperature.

The strikingly marked Golden-tailed Gecko (*Strophurus taenicauda*) is an arboreal species, restricted to the Brigalow Belt bioregion of the southeastern interior of Queensland. It inhabits dry forests, favoring associations of eucalypt, native pine (*Callitris*), and various species of acacia, particularly Brigalow (*Acacia harpophylla*). There are three described subspecies, differing in scalation details but also readily identifiable by coloration (Brown et al. 2012. Zootaxa 3243:1–28). The lizard pictured is the nominate subspecies, *S. taenicauda taenicauda*, which has ruby red eyes, dense black speckling, and a wavy-edged tail stripe. Other races have grey to amber eyes, straight-edged stripes, and finer black spotting.

Golden-tailed Geckos are of conservation concern and are listed under Queensland Government legislature as "Near threatened." Though very common in their habitat, native vegetation throughout the bioregion is declining and fragmenting through clearing for agriculture and grazing, inappropriate fire regimes, weed and feral animal invasions and, more recently, a rapid expansion in the exploitation of coal and natural gas.

This lizard was photographed by Australian herpetologist **Steve Wilson** at Lake Broadwater in southeastern Queensland. Steve mounted a Canon 30D and a Canon 100mm lens on a tripod to capture the image at a shutter speed of 0.6 second with natural daylight at ISO 100 and an aperture of f16. Steve has written field guides to reptiles of Australia and his home state of Queensland, a guide to reptiles of the southern Brigalow Belt, and a reptile book for children. His most recent book (*Australian Lizards: A Natural History*. CSIRO Publishers, Collingwood, Victoria. 208 pp.), published in 2012, is a popular guide to Australia's remarkable lizard fauna.

PHOTO BY MARILYN PARKER

CELEBRATING THE 7TH WORLD CONGRESS OF HERPETOLOGY

• NOW PUBLISHED! •

ERPÉTOLOGIE GÉNÉRALE

ou Histoire Naturelle Complète des Reptiles

Constant Duméril

Gabriel Bibron

Auguste Duméril

AMONG THE PUBLISHED WORKS IN herpetology over the last five centuries, only two can be said to cover all known species of amphibians and reptiles comprehensively and scientifically. One, in English, was by George A. Boulenger and based on the collections of the British Museum in London (9 volumes, 1882–1896). These books were reprinted in 1961–1966 and, despite their age, remain among the most frequently consulted references in herpetology. The other, in French, was by Constant Duméril, Gabriel Bibron, and the senior author's son, Auguste Duméril, and based on the collections of the Muséum d'Histoire Naturelle in Paris (9 volumes plus an atlas of colored plates, 1834–1854). This latter work, generally known as "D & B," has never been reprinted, yet it remains of continuing value to a broad community of academic zoologists, museum and zoo curators, and conservationists, and especially to herpetologists working in developing countries. D & B is, in fact, more comprehensive than its English counterpart, for in addition to having more detailed descriptions of genera and species, it also covers the internal anatomy, physiology, and the associated literature.

Karl Patterson Schmidt, a leading American herpetologist, wrote: **"The *Erpétologie Générale* was the crowning work of a century of herpetological studies, during which the leadership in the field had lain with the French."** At that time, Paris was the epicenter of world science and its museum boasted the greatest naturalists: Buffon, Geoffroy Saint-Hilaire, Lacepède, Lamarck, and the greatest of them all, Georges Cuvier. Also among them was Constant Duméril, who trained as a physician and became one of Cuvier's closest colleagues. The Paris museum then possessed the largest natural history collections in the world. D & B was the first work in which a natural arrangement of genera was attempted, and many of the genera and species were first described there.

This full-size facsimile is complete and carefully edited for clarity. The 120 finely executed plates are reprinted in *both uncolored and colored states* because the original coloring sometimes obscures details of scutellation. The nine text volumes, which total nearly 7,000 pages, and the atlas of 240 plates are sturdily bound in library-grade cloth and printed on durable, acid-free paper. The **new introduction by Roger Bour (Paris)** is an in-depth review of the book (including exact publication dates) with new biographies of the three authors. A **comprehensive index to the scientific names**, missing in the original book, has been added. The original book was issued in fewer than 500 sets; a colored set, rarely offered today, costs about US$15,000. Only 400 new sets are being reprinted. (This reprint is being offered at an affordable price because of a generous subsidy from Ronald A. Javitch of Montréal.) Herpetological centers in developing countries are invited to contact the editor (*Kraig Adler*: kka4@cornell.edu) about special arrangements for obtaining copies.

■ SPECIFICATIONS: Nine volumes (bound in five) of text, plus an atlas volume of 240 plates (in colored and uncolored states), all 5½ × 8½ inches (14 by 21.5 cm). Library-grade cloth bindings. ISBN 978–0–916984–87–8. ***Issued December 2012***.

■ PRICES: • **Regular Price:** $275. • **Special Price to SSAR members** (if order is received before 31 January 2013): $225. • **Shipping**: USA address, add $15; non-USA shipping at cost. • **Orders to:** SSAR Publications Secretary, P.O. Box 58517, Salt Lake City, Utah 84158–0517, USA (*telephone and fax*: 801–562–2660; *e-mail*: ssar@herplit.com). • **Payment:** Make checks payable to "SSAR." Non-USA orders must be paid in USA funds using a check drawn on an American bank or by International Money Order. Books may be charged to American Express, Discover, MasterCard or Visa (please give account number and expiration date). • SSAR Membership and Other Publications: Membership information and a list of society publications can be obtained from the Publications Secretary at the address given above or at www.ssarherps.org.

SSAR BUSINESS

SSAR Election Results

Results of the 2012 SSAR election are as follows:

President-Elect: Aaron Bauer
Treasurer: Ann Paterson
Secretary: Marion Preest
Board Members (Regular): Frank Burbrink, Lisa Hazard, Greg Watkins-Colwell
Board Member (non-US): Alison Cree

Thank you to all of the nominees who agreed to stand for positions and to Dan Noble (Elector).

Seibert Award Winners for 2012 Announced

The 21st annual Seibert Awards were presented at the 55th Annual Meeting of the SSAR (held in conjunction with the 7th World Congress of Herpetology) in Vancouver, Canada, 8–14 Aug 2012. These awards are named in honor of Henri C. Seibert, an early and tireless supporter of SSAR (having served as an officer for over 20 years). In recognition of outstanding student presentations at the annual meeting, a single award was given in each of the following categories: Evolution/Systematics (12 presentations), Ecology (22 presentations), Physiology/Morphology (8 presentations) and Conservation (11 presentations). All awardees will receive a check for US $200 and a book from Chuck Crumly at University of California Press.

The Winners.—Systematics/Evolution: **Sara Ruane** (College of Staten Island), "Speciation in the Milksnake (*Lampropeltis triangulum*)." Ecology: **Thomas Luhring** (University of Missouri), "Islands in the Sun: Nutrient Cycling is Isolated Systems is Mediated by Canopy Cover, Predation, and the Complex Life-Histories of their Transient Tenants." Conservation: **Shawn McCracken** (Texas State University, San Marcos), "Living on the Edge: Oil Road Effects on the Occupancy and Abundance of Anurans Inhabiting an Upper Canopy Tank Bromeliad (*Aechmea zebrina*) in Lowland Rainforest of the Yasuni Biosphere Reserve, Amazonian Ecuador." Physiology/Morphology: **Rory Telemeco** (Iowa State University), "Effects of Temperature During Development on the Offspring Phenotype of a Facultative Thermoregulator, the Southern Alligator Lizard (*Elgaria multicarinata*: Anguidae)." Honorable Mentions were given to **Gareth Hopkins**, **Julia Riley**, and **Hilton Oyamaguchi**.

The judges were Chris Parkinson, Andrew Crawford, Traci Rittenhouse, Doug Eifler, Eric Juterbock, Caren Goldberg, Edgar Lehr, Pete Zani, and Rafe Brown (chair).

SSAR Student Poster Awards

The SSAR Poster Awards will provide recognition for the best student posters presented at the annual meeting of the SSAR. To be eligible, the presented poster must be the result of research conducted by the individual making the presentation. The research must have been conducted while the student was enrolled in either an undergraduate or graduate degree program. Students entering the competition must be members of SSAR. The presentations will be judged by the SSAR student prize committee. One SSAR Poster Award of U.S. $100 may be given in each of the following four categories:

- Evolution, Genetics, & Systematics
- Ecology, Natural History, Distribution, & Behavior
- Physiology & Morphology
- Conservation & Management

The SSAR Poster Award will be judged by the following criteria:

- Quality of Research
- Quality of the Visual Display of the Research
- Professionalism and Confidence of the Presenter

Students may win the award only one time. Please indicate the appropriate category for which you are applying on the abstract submission form. Contact Tiffany Doan at tiffperu@yahoo.com or 860-839-2944 for further information.

Recommendations to Students Entering the SSAR Poster Competition

The SSAR Poster Award was presented for the first time at the 2011 Joint Meeting. The SSAR Board of Directors wishes to recognize that poster presentations are an important part of the annual Joint Meeting event and that they are an important component of the graduate and undergraduate experience. The presentation of some research projects is better suited to a poster session, which allows much greater communication between the presenter and the audience. The following recommendations are intended to aid students in improving the quality of their poster presentations. The criteria presented below are applicable to any poster given at a scientific meeting.

Preparing the Presentation

A. The Poster Itself

- More so than an oral presentation, a poster needs to visually draw in the audience. When hundreds of posters are up at the same time, one's poster needs to stand out to be noticed.
- Organization is key—a cluttered poster that is hard to read will not keep the attention of the audience.
- Use large fonts: at least 28–36 size font for the smallest words; approximately 90 size for the title.
- Use *sans serif* fonts such as Arial, Helvetica, and Calibri, which are easy to read from a distance.
- Use as many figures as possible, including graphs and photographs, to display your data.
- Use color to your advantage, but do not make it overwhelming. No one wants to look at a black-and-white poster, but too much color can be distracting.
- Do not include paragraphs on your poster (no one wants to stand there and read them). Bullet points or short sentences are much easier to read.

B. Oral Presentation

- Prepare a short explanation to your poster so that viewers do not have to read everything.
- Anticipate questions that the audience might have.
- Be prepared to discuss further research that you may later perform based on the results from the project about which you are presenting.

- Remember that other scientists have stopped at your poster because they are interested in your research. Relax and enjoy the experience of "talking shop" with other scientists who share similar interests.

Describing your Research

A. Design

- Present your research in a larger context by addressing previous studies (choose 1 or 2 to make your point). Relate your data to the knowledge of your field.
- Clearly state your hypothesis(es) and/or objectives up front.
- Flag techniques that are original to your study (i.e., this study is the first to address this question or to use this technique).

B. Summary of Results

- Present your results clearly. Tables with N and P values are fine (but not necessary) if they are readable. Always indicate your sample sizes.
- Indicate the importance of your results. How do they relate to previous studies? Biology in general?

C. Importance of Study

- An abstract, summary, or conclusions section of your poster is helpful in tying together many results.
- State the importance of your study and how your research has added to knowledge of the subject presented. Are your results generally applicable to larger biological questions?

2012 Annual Meeting, Vancouver, British Columbia, Canada

The 55th Annual Meeting of SSAR took place from 8–14 August 2012 on the campus of the University of British Columbia in Vancouver, British Columbia, Canada. This meeting was held in conjunction with the 7th World Congress of Herpetology (Aaron Bauer, Secretary General). WCH has previously met in the United Kingdom, Australia, the Czech Republic, Sri Lanka, South Africa, and most recently, in Brazil. This was the first WCH to be held in North America and the first to include ichthyological colleagues from ASIH and AES. Organizing societies this year were the World Congress of Herpetology, Society for the Study of Amphibians and Reptiles (along with the International Society for the History and Bibliography of Herpetology), American Elasmobranch Society (celebrating its 28th annual meeting), American Society of Ichthyologists and Herpetologists (celebrating its 92nd annual meeting) and The Herpetologists' League (celebrating its 70th annual meeting). Pat Gregory was the hard-working chair of the Local Organizing Committee and David Green was chair of the Scientific Program Committee. They were ably assisted by other members of both committees and a host of local volunteers. Special thanks to Sheri Donavan (of "Conferences and Accommodation at UBC") and others in her team.

The meeting included 133 sessions, with 25 symposia on topics as diverse as "Habitat Fragmentation," "Caecilian Biology," "Reintroductions and Translocations," "Insights from the Fossil Record," and "Biogeochemical Methods in Ecology." SSAR sponsored two symposia: "Technology and Innovations in Collections" and "Invasive Species and Global Change" (Fig. 1). Around 1040 oral presentations and 430 poster presentations were made. Each day began with a plenary session, followed by multiple oral presentation sessions, and then a poster session beginning at 5 pm (Fig. 2).

SSAR was the sole Gold Level Sponsor of the WCH, as well as a contributing society. Other sponsors and contributors included LGL Limited- Environmental Research Associates, University of Victoria, Wildlife Acoustics, UBC Faculty of Forestry, Beaty Biodiversity Museum, Canadian Association of Herpetologists, Canadian Amphibian and Reptile Conservation Network, The Herpetologists' League, ASIH, and AES.

David Dennis produced a striking poster that was distributed *gratis* to all delegates. The image is of a frog with tadpoles and eagle heads and is based on Pacific Northwest aboriginal designs from the Haida cultural group. Thanks to Jim and Sarah Christiansen who sponsored the poster. A version of the poster in multiple languages was used to welcome delegates from around the world to WCH (Fig. 3). This was one of many elements of SSAR's contribution to the Congress, emphasizing our commitment to WCH from its very beginnings, and to demonstrate our status as a truly international society. Also included in the delegate bags were copies of *Herpetological Circulars* 39 and 40 (7th edition of the *Scientific and Standard English Names of Amphibians and Reptiles of North America North of Mexico* and *Noms Français Standardisés des Amphibiens et des Reptiles D'Amérique du Nord*

WCH 7 Posters Available

The official SSAR poster that welcomed delegates to the 7th World Congress of Herpetology in Vancouver in August 2012 is available in limited quantities. Each poster measures 11 x 17 inches and can be purchased from the SSAR Publications Office for $4.00 each postpaid or $3.00 in quantities of 10. Posters cannot be shipped outside the USA because of their size.

Orders or inquiries to:
Breck Bartholomew, SSAR Publications Secretary
Post Office Box 58517, Salt Lake City, Utah 84158-0517, USA
Telephone and Fax: (801)562-2660, e-mail: ssar@herplit.com

FIG. 3. A version of the poster designed by David Dennis and given to delegates at WCH.

Au Nord du Mexique / Standard French Names of Amphibians and Reptiles of North America North of Mexico), the special June 2012 "Congress" issue of *Herpetological Review*, "Contributions to the History of Herpetology, vol. 3," and a recently produced membership brochure. Thanks to the many individuals (e.g., Kraig Adler, Breck Bartholomew, Bob Hansen, John Moriarty) who made all of this possible.

After a busy day of Board and Executive Committee meetings, the 2012 WCH began officially with a Plenary Session on the morning of Aug 9th. Pat Gregory and David Green, local organizing chairs, gave us a warm welcome to Canada (Fig. 4). Pat mentioned that the idea for a WCH in Canada began back in 2002 at the JMIH meeting in Kansas City, Missouri. Pat reported that nearly 1,700 herpetologists and ichthyologists from at least 48 different countries were in attendance. This makes it the largest WCH yet! Approximately 44% of the attendees were students. Pat couldn't resist informing us that Canada was "punching above its weight" relative to the United States, i.e., the US has 10 times the population, but only 5 times the number of herpetologists at WCH! He also pointed out Canada's Summer Olympics bronze medal win in women's soccer that same day. Pat acknowledged the hard work of Sheri Donavan and her colleagues.

WCH Secretary General, Aaron Bauer, then welcomed SSAR, ASIH, HL, and AES to the WCH. He reserved a particular welcome to those who had traveled long distances. Aaron went over details of WCH business meetings occurring over the next few days. Angela Redish (Vice Provost and Associate Vice President of Enrollment and Academic Facilities) welcomed WCH to the UBC campus. She provided some information about the University and highly recommended that we visit the Beaty Biodiversity Museum and the Museum of Anthropology.

The first plenary presentation for the morning was by Tyrone Hayes (University of California, Berkeley)—"THE Cause of Amphibian Decline" (Fig. 5). Tyrone introduced himself as the "little boy who likes frogs" and spent the next 45 minutes explaining his self-acknowledged "obnoxious" title. He spoke extensively about his experimental laboratory work with atrazine and studies on atrazine in the field. He also spoke about how he regarded being referred to as an environmentalist, not as a slur, as sometimes intended, but rather as something to aspire to. Tyrone finished with a quote from Einstein: "Those who have the privilege to know have the duty to act."

SSAR, ASIH, and HL then announced Michael Dorcas as the third recipient of the Meritorious Teaching Award in Herpetology. Mike received a plaque and a cash award. ASIH representatives

FIG. 13. Attendees at the student workshop—standing room only!

presented a number of awards (the Robert Gibbs Award to Lance Grande, the Fitch Award to Jonathan Campbell [Fig. 6], and the Johnson Award to Brooks Burr).

Michael Douglas, ASIH Past-President, made time for a slide-show tribute and eulogy to Joe Nelson by his wife Claudine and then gave a short presentation on "Riverside Genetics as a Conservation Tool in Southwestern North America."

The Canadian Association of Herpetologists presented the Rankin Distinguished Herpetologist Award to Richard Wassersug, and the Canadian Amphibian and Reptile Conservation Network presented its Blue Racer Award to Jim Bogart. The second plenary speaker for the first morning, Karen Warkentin, was introduced by Pat Gregory. Karen spoke about "Environmentally-Cued Hatching: Integrative and Evolutionary Biology." She began by reminding us that most organisms begin life as eggs, that selection on embryos and hatchlings varies, and that eggs provide benefits, but also impose constraints. She made the point that embryos should hatch when the benefits of being outside an egg exceed the costs. Karen then began speaking about the two decades she has spent working with Red-eyed Treefrogs after discovering that embryos can hatch as much as 30% prematurely in response to predation cues. She spoke about other sources of mortality that can induce early hatching, the consequences of this early emergence, and the role of various kinds of vibrations on hatching. Pat Gregory wrapped up the first plenary session shortly before noon with concluding remarks and more announcements.

Shorter plenary sessions were held each morning with great talks each time. On 10 August, Lara Ferry, the AES invited speaker, talked about "Elasmobranchs in Biological Research" and Susan Evans gave a talk entitled "On the Evolution and Early History of Lepidosaurian Reptiles." The next day, the speaker was Laurie Vitt ("Walking the Natural History Trail"), and on 12 August, Mark-Oliver Rödel spoke about "West African Amphibians: Diversity, Threats, and Future." Kelly Zamudio was the final plenary speaker of the 7th WCH and she spoke about "Diversification and Conservation of Reptiles and Amphibians: Genomes, Populations, and Landscape."

Social and Professional Events

Harry Greene was this year's much-anticipated SSAR President's Travelogue speaker (Fig. 7). To say that there was standing room only for his presentation ("Natural History, Aesthetics, and Conservation") would be an understatement. After an introduction from President Mendelson and some technical difficulties (which he handled with a good-humored quip "just be glad it's happening to me and not you"), Harry got underway. He spoke about how science inspires values, the distinction between beauty and sublime, how we can all be teachers, and of the significance of his "three favorite things—a rolling pin, a book, and a rifle." He then focused on frog diversity and the "froginess" of these organisms as jumping machines. Next he spoke about the relationship between snakes and primates ("snakes eat primates, primates eat snakes"), the approximately 75 million years of "conflict" between these groups, and some of his work with Black-tailed and Timber Rattlesnakes. Harry finished up with a story of a discussion about *Crotalus atrox* that he had years ago with a cowboy in a Texas bar.

The SSAR/HL Student Reception was held late afternoon on 9 August. The room was packed with students and invited professional herpetologists. President Mendelson gave a warm welcome to our student members and encouraged them to enjoy finger food, drinks, and meeting senior herpetologists. Thanks to those who donated door prizes and congratulations to the lucky winners. A special thanks to Ronn Altig who provided handmade wooden coasters/medalions imprinted with the SSAR congress frog, as gifts to the students. The student reception was followed by the WCH Welcome Reception on a field near the halls of residence where most attendees stayed. In addition to good food, there were games of minigolf, volleyball, fooseball, boci ball, and croquet (Figs. 8–10).

Erin Muths was the lead organizer of a lunch-time student workshop on "Thesis Chapter to Published Manuscript AND Participating in the Peer-Review Process" (Fig. 11). Other participants were Chris Beachy, Robert Hansen, Robert Jehle, Brad Moon, Gad Perry, and Benedikt Schmidt (Fig. 12). Pizza and sodas were provided (as promised, we didn't run out this year! Barely….. one piece of pizza and four sodas were left) and students were lined up outside the room before the workshop began (Fig. 13). The organizers had produced a detailed and polished 85-slide Powerpoint presentation. They spoke, and answered questions, about such issues as the importance of publication, preparing manuscripts, understanding the review process, interpreting reviews, revisions, and becoming a peer-reviewer. At least 83 students attended. Discussion by the editors after the workshop included decisions to post the Powerpoint presentation from the workshop on the websites of HL and SSAR and the European societies and to consider presenting the workshop every 3–4 years.

The SSAR/HL live auction was held on 12 August. Although it was never going to live up to last year's Ernie Liner Auction, it was still well attended and good fun and we raised $5,800. All proceeds will be donated to the WCH. Auctioneers Steve Mullin, Frank Burbrink, Robert Fisher, and Jose Lefebvre were ably assisted by Greg Watkins-Colwell and a number of hard-working students (Heather M. Heinz, Matthew H. Shirley, Max Lambert, Madeline Miguel, Nassima Bouzid, James Titus-McQuillan, and Johana Goyes Vallejos; Figs. 14 and15).

Mike Jorgensen and Vinny Farallo once again organized the Silent Auction. The silent auction items were set up in the lobby of the main halls of residence for the meeting (Fig 16). A particular thank you is due to Shifra Laskier Levene, Dave Bickford, David and Marvalee Wake, and Sinauer Press for their donations. A big-screen TV with 24-hour Olympics coverage was nearby, so the silent auction desks enjoyed plenty of traffic. Once again, the ten recipients of the $400 SSAR Student Travel Award (Fig. 13) took turns to work the silent auction table for 2–3 h throughout the course of the meetings.

The WCH Plenary Business Meeting was held on the evening

of 12 August. The main topic of discussion was the location of the next WCH. Proposals had been received for four venues - Kusadasi (Turkey), Hangzhou (China), Florence (Italy), and Cairns (Australia, a joint bid from Australian and New Zealand delegates). Representatives for each of these bids made their case, and discussion of the merits of each followed. There was a non-binding vote and then in a closed session the Executive Committee made the final decision.

The meeting ended with a picnic on the grounds of the Museum of Anthropology on the UBC campus (Fig. 17). Gone was the formality of recent JMIH banquets. Attendees had the pleasure of viewing the amazing indoor and outdoor exhibits at the museum before and after dinner (Fig. 18). The food (a buffet) was excellent and the live music much enjoyed. It was announced that China has been selected as the venue for the next WCH. The China Herpetological Society and the Asian Herpetological Society invite the world's herpetologists to attend the 8th WCH in Hangzhou, China, 2016.

Board and Business Meeting Summaries

SSAR Board Meeting

Society President Joseph Mendelson called the Board Meeting to order at 0808 h on 8 August 2012 in the Student Union Building on the UBC campus. In attendance were the following members of the Board of Directors, Editors, and Committee Chairs: Kraig Adler (Editor, *Contributions to Herpetology*; Chair, Long Range Planning Committee), Bob Aldridge (President-Elect), Breck Bartholomew (Publications Secretary), Aaron Bauer (Editor, *Facsimile Reprints in Herpetology*), Rafe Brown (Chair, Seibert Award Committee), Brian Crother (Past-President), David Cundall (Board Member, Reg. 2012), Kevin de Queiroz (Board Member, Reg. 2012), Tiffany Doan (Board Member, Reg. 2014), Richard Durtsche (Coordinator, Symposium Committee), Vincent Farallo (Chair, Silent Auction Committee), Pat Gregory (Board Member, non-US 2012), Robert Hansen (Editor, *Herpetological Review*), Josh Kapfer (Chair, Roger Conant Grants-in-Herpetology Committee), Travis LaDuc (Board Member, At Large, 2014), Joseph Mendelson, III (President), Joe Mitchell (Editor, *Herpetological Conservation*), Erin Muths (co-Editor, *Journal of Herpetology*), Kirsten Nicholson (Treasurer), Dan Noble (Elector), Gad Perry (co-Editor, *Journal of Herpetology*), Jennifer Pramuk (Board Member, Conservation, 2014), Marion Preest (Secretary), Al Savitzky (SSAR Representative to AIBS and BioOne), Carol Spencer (Board Member, Reg. 2014), Greg Watkins-Colwell (Chair, Nominations Committee; Organizer, SSAR/HL Live Auction). Additional society members present included Jim Christiansen, Marina Gerson, Steve Godley, Hinrich Kaiser, Roy McDiarmid, Henry Mushinsky, Wulf Schleip, and Jackson Shedd. Introductions were made and minutes of the 2011 Board of Directors Meeting (Minneapolis, MN) were approved.

Annual reports for 2011/2012 were submitted by most Officers, Editors, and Committee Chairs.

Officers' Reports.—President Joe Mendelson reported that SSAR recognized the following individuals with Special Recognition awards: Andrew Price, Marion Preest, Chuck Crumly, Ronald Javitch, Breck Bartholomew, and David Chiszar. Condolence letters were sent to the families of Andrew Price and Joseph T. Collins. Acknowledgment letters were sent to Jim Christiansen and Wendy Hodges and award letters were sent to the recipients of the Roger Conant Grants-in-Herpetology Awards and

the Andrew Price Field Research fund. The President wrote two "state of the union" type essays about SSAR-related matters that were published in *Herpetological Review*. Minor JMIH-related business was attended to this year, in relation to the planning of meetings for 2013 and 2014. Working closely with David Dennis, Kraig Adler, Ronn Altig, Breck Bartholomew, and Pat Gregory, significant efforts were put toward preparation of various *gratis* and promotional materials related to the 2012 World Congress of Herpetology. Harry Greene accepted an invitation to be the 2012 President's Travelogue presenter. The President acted as the voice of SSAR for numerous requests for information related to herpetology and/or SSAR, and also acknowledged an overwhelming number of compliments from members and colleagues regarding the reformatted appearance of *Journal of Herpetology* and *Herpetological Review*. Completion of the electronic index for *Herpetological Review* was anticipated for January 2012, but is not quite complete as of the time of this report. The President worked with Kris Kaiser, Andrew Durso, and Marion Preest to conceptualize and launch the new Mentorship program for the annual meetings. The President also engaged in ongoing discussions with relevant editors and officers related to matters of Conservation Committee letters, page charges for journals, the website, and the future of the CAAR publication series.

Treasurer Kirsten Nicholson reported that, overall, the finances of SSAR continue to be sound despite ongoing global economic issues combined with recent changes to our dues structures and journal formats. Overall we underspent our budget this year (by just over $110,000). Several changes were made to our journal formats, but all costs were covered within expected limits. Our investment portfolio went down over the course of 2011, but has come back well over 2012 and we are hovering at the value of our investments' totals from 6 years ago. Kirsten reported that the market value of our investments at the end of 2011 was $560,053, but as of June 2012 has increased to $605,478. Membership numbers are down slightly, but not significantly, and thus our numbers seem to be holding steady in the light of the economy combined with a dues increase. This will allow us to continue to provide high quality publications and serve our membership by supporting their research and presentation endeavors. SSAR accepted extremely generous donations during 2011 and 2012 for various projects that are underway currently or have been recently completed, and these have added to our financial security.

Kirsten reported that Breck Bartholomew's membership management for the society has been a fantastic and welcome change and has cost us very little. Breck takes a 10% commission on membership income as payment for his services to us which is well due and likely much less than he should be paid, particularly given the work that is going into processing and selling all of the estates that have recently been bequeathed to SSAR.

Secretary Marion Preest provided Officers, Editors, and Committee Chairs with minutes of the 2011 Board Meeting and summarized the 2011 Annual Meeting for publication in *Herp. Review*. She keeps track of changes in personnel and regularly updates SSAR letterhead, informs the Editors of *Journal of Herpetology* and *Herp. Review* of these changes, and provides various updates to Raul Diaz. She routinely writes letters to student winners of awards (e.g., Kennedy, GIH, etc) and prepares announcements for publication in *Herp. Review*. Marion compiled the 2012 Annual Report and prepared agendas for the Board and Business Meetings for the 2012 Annual Meeting. She again organized a reception for student members of SSAR and HL to be held at the WCH. Marion corresponded with the Board regarding various issues that needed a vote, e.g., naming the Grants-in-Herpetology Awards after Roger Conant, funding of proposals for upcoming symposia, a resolution from the Amphibian Survival Alliance, support for the Global Reptile BioBlitz, changes in dues structure, changes in page charges for *Journal of Herpetology*, proposals from the LRPC, etc. As an *ex officio* member of the Nominations Committee Marion helped to identify and contact potential candidates for the six positions we need to fill in 2012. She also served on the new Mentorship Committee (chaired by Kris Kaiser).

Publications Secretary Breck Bartholomew reported that total income from the Publications Office in 2011 was $40,644.43. Income generated as of 30 June 2012 was $60,482.67. He is requesting a budget for 2013 of $43,660. This includes funds to pay an employee to list items from the Ernie Liner Collection. All expenses associated with the collection will be covered by the sale of the collection before it is distributed to HL and ASIH. Breck indicated that the library of Roger Conant is selling well. There was discussion by the Board of E-reader versions of herpetology books and some interest was expressed. Thanks to Jeff Miller, scanned pdf versions of back issues of *Herp. Review* are now

FIG. 18. Museum of Anthropology.

available to members. There was some discussion of whether these files should be made open access.

George Pisani (Trustee) reported that he again filed SSAR's annual corporate report with the Office of the Kansas Secretary of State.

Editors' Reports.—Kraig Adler, *Contributions to Herpetology* Editor, reported that "*Snakes of Honduras*," by James R. McCranie and "*Herpetology of Armenia and Nagorno-Karabakh*," by Marine Arakelyan, Felix Danielyan, Claudia Corti, Roberto Sindaco, and Alan Leviton were published in 2011. "*A Contribution to the Herpetology of Northern Pakistan*" by Rafaqat Masroor was published in early 2012 and "*Contributions to the History of Herpetology,*" the third and final volume, by Kraig Adler, John S. Applegarth, and Ronald Altig was published in August of this year (this was included in the bags of all delegates at WCH). Both of the 2012 publications were supported by generous donations. "*A Guide to the Snakes of the Philippines*" by Rafe Brown, Alan Leviton, Maren Gaulke, and Arvin Diesmos is expected in 2013 and "*Field Guide to Amphibians and Reptiles of the West Indies*" by S. Blair Hedges, and "*Lizards of Southern Africa*" edited by William R. Branch and Aaron Bauer are planned beyond 2012.

Editor Aaron Bauer (*Facsimile Reprints in Herpetology*) reported that a major publication is planned for Dec. 2012 (Duméril and Bibron's "*Erpétologie Générale ou Histoire Naturelle Complète des Reptiles*" [1834–1854] [to be guest edited by Kraig Adler]). This is one of the most important of all herpetological works and a truly comprehensive summary of all amphibian and reptile species known at the time. It is global in scope and contains descriptions of many species. Only relatively poor pdfs are available on the web, despite the fact that this is a critical reference for systematists. The work totals nearly 7000 pages with a separate Atlas of 120 plates. As the result of a generous donation from Ronald Javitch, Aaron expects to be able to sell this *Facsimile* at US $275 (US $225 before 31 January 2013 to current members of SSAR) plus postage. The majority of projects planned beyond 2012 (e.g., The Herpetological Contributions of John Edward Gray, The Collected Herpetological Works of Giorgio Jan) are in various stages of completion and only one publication is planned per year for the foreseeable future.

John Moriarty (Editor, *Herpetological Circulars*) reported that HC-39 (Seventh Edition of the *Scientific and Standard English Names of Amphibians and Reptiles of North America North of Mexico*) will be given away at the World Congress in Vancouver. HC-40 (*Noms Français Standardisés des Amphibiens et des Reptiles D'Amérique du Nord Au Nord du Mexique / Standard French Names of Amphibians and Reptiles of North America North of Mexico*) will also be given away at the WCH as a companion to the 7th edition. HC-41 A *Guide to Tissue Collection, Preservation, and Management for Reptiles and Amphibians* is in prep, but has been postponed because of the publication of the names lists and the author's schedule.

Editor of *Herpetological Conservation*, Joe Mitchell reported that little progress has been made in the past year on a possible project for the next publication and acknowledges that it is time we make this series more visible.

Robert Hansen, Editor of *Herpetological Review*, reported that Volume 42 consisted of 632 pages (a 27% increase since 2009) and Volume 43 is projected to run over 700 pages. Personnel changes include Associate Editor Kerry Griffis-Kyle stepping down at the end of 2012 and Daniel Saenz joining the staff. Jay Savage proposed the addition of a new section ("Herpetological Nomenclature"), for which he agreed to serve as Section Editor; this debuted in the June 2012 issue. Beginning in 2011, *Herp. Review* initiated two new sections: "Conservation"—to better reflect the importance of conservation-related issues in herpetology, and "Herpetoculture Notes"—to accommodate interesting and often important observations that are not always a good fit for our Natural History Notes section. Bob reports resurrecting a long-dormant feature—"Institutional Profiles"—with the first contribution appearing in the June 2011 issue. Another section—"National and Regional Organizations"—also saw its first installment in 2011.

The "Amphibian Diseases" section in *Herp. Review* was conceived in 2007 as a means to facilitate the rapid communication of chytrid-related findings in amphibian populations. The number of manuscripts by year is as follows: 2007 (9), 2008 (23), 2009 (18, including the first *Ranavirus* paper), 2010 (27), 2011 (25). Although nearly all of the early papers focused exclusively on *Bd*, about 40% of current submissions are reporting on *Rv*. This herculean effort has been made possible by the assistance of 224 reviewers. Submissions are broadly international in scope, including manuscripts from Australia, Finland, Denmark, India, Cambodia, Malawi, Ghana, Nigeria, Morocco, Gabon, Jamaica, Honduras, Costa Rica, Panama, Bolivia, Uruguay, Peru, Colombia, Canada, Ecuador, Brazil, Venezuela, Taiwan, Italy, Congo, Czech Republic, and Mexico, in addition to 29 U.S. states or territories. Many international collaborations are represented by this body of work. These papers are being referenced in many other disease papers in other journals, so we are having a big impact. *Bd* survey sites are mapped by the Global *Bd* Mapping Project (www.Bd-maps.net) managed by personnel at Imperial College, London. *Rv* sites will be mapped with the *Rv* Reporting System, under development now, in cooperation with *Rv* Consortium and Imperial College, London.

The June 2012 *Herp. Review* was a special issue to commemorate the 7th WCH. The centerpiece of this effort was a WCH history, from its earliest beginnings through the 6th WCH. Kraig Adler was instrumental in helping pull this together, and Breck Bartholomew and Ken Dodd also contributed. The end result is an 18-page retrospective—the only history of the WCH published to date. In addition to the WCH history, in light of our Canadian venue for the meeting, Pat Gregory and David Green (current and former Presidents, Canadian Association of Herpetologists) were invited to prepare a current overview of the status of herpetological organizations in Canada. The June issue—at 196 pages—is our largest ever, and was distributed *gratis* to all delegates at Vancouver.

Co-editors of *Journal of Herpetology*, Erin Muths and Gad Perry, report that former Editor Geoff Smith remains as Associate Editor (AE) for special projects, but no longer serves as "Interim Editor." The AE roster at the end of 2011 contained four new names and many continuing ones. Despite considerable efforts and public appeals made at the 2011 JMIH meeting, expanding the AE base, especially by adding colleagues from other countries, remains a challenge. The editors report that two of their personnel were explicitly told that their editorial involvement was damaging to their professional careers, and one has chosen to reduce their contribution. Several potential AEs contacted expressed similar concerns when declining the position. Erin and Gad fear that this reflects an institutional change in Academe as a whole, whereby service is discouraged in favor of revenue-enhancing activities.

Overall submissions to *JHerp* declined slightly in 2011, compared to the record level set in 2010. Submissions so far for 2012 (178 as of the end of June) are slightly higher than the number

submitted during the same period in 2011. The amount of time needed to reach initial and final decisions remains similar to the past few years. The biggest challenge to reducing handling times is obtaining timely reviews. Unfortunately, the wait between acceptance of a paper and publication rose in 2011 from approximately 9 to 12 months. This is primarily a function of the record submission level in 2010. As part of their desire to increase the international flavor of the journal, Erin and Gad report that they were more lenient towards foreign manuscripts in early 2011, and the slightly lower rejection rate also contributed to the problem of handling time. They have taken steps to address this, including instructing AEs to reject a greater proportion of submissions, more aggressively forcing authors to address linguistic and formatting issues prior to review, and planning an especially large December issue.

The US remains the leading source of manuscripts (~ 40% of all submissions), and Brazil remains the second highest source (> 12% of submissions). Australia, with ~ 7% of submissions in 2011, is also a consistent source of manuscripts. Of countries with sufficient submissions to assess, the US and Australia have relatively high acceptance rates and Brazil is not far behind. Erin and Gad added a Brazil-based AE in 2011 and are currently seeking one from Australia. President Mendelson expressed appreciation for the increased internationality of the journal. Erin and Gad regard the Editorial Board as still under-utilized, although they have been using them to a slightly greater extent. They are currently assessing the group and will determine if additions or other changes are necessary. Letters have been sent to current members to ascertain interest in remaining on the Board.

According to the Allen Press "Member Submissions Report," 35% of submissions in 2011 had one or more authors who are SSAR members, compared to an average of 38% in the previous five years. Journal quality, as reflected by the ISI Impact Factor and total citations reported, remains good in comparison to other journals in the field, with *JHerp* consistently remaining the most cited herp-only journal.

Comments received by Erin and Gad regarding recent changes have been positive. Changes include a larger paper format, implementation of an optional second-language abstract, inclusion of invited long-term perspective papers, inclusion of special "focus" features, uniting related papers in a single section for easier location and visibility, abandonment of a format distinction (use of different font size) between Notes and Full Papers, and inclusion on the back cover a world map to indicate countries of origin for papers appearing in that issue.

Starting in 2010, the co-Editors attempted to provide a complete accounting of *JHerp* income and expenses, rather than just their approved budget. Some of the decisions the co-Editors are asking the Board to make require a better understanding of where journal-related costs and income originate. As of this year, *JHerp* invoices are copied to Erin and Gad as they are sent to the Treasurer.

Committee Chair Reports.—Chair of the Conservation Committee, Betsie Rothermel, reported that in November 2011, the Committee sent comments to the U.S. Fish and Wildlife Service regarding proposed critical habitat for the endangered Mississippi Gopher Frog. As in earlier comments on this issue, the Committee supported the move to designate critical habitat, including areas outside the current range of the species to enable future reintroductions, and they argued for increasing the area of the buffer around existing breeding sites. In January 2012, the Committee sent a letter to organizers of the Claxton Rattlesnake and Wildlife Festival in Georgia praising them for their decision to change the focus of the festival and suspend the collection of wild snakes for the March 2012 event, initiating a break with the 44-year-old tradition of annual rattlesnake roundups. In May 2012, the Committee submitted comments to the U.S. Environmental Protection Agency regarding the effects of atrazine on amphibians. They urged the EPA to re-evaluate its earlier findings in light of recent research results regarding effects of atrazine on larval development, survival, interactions with parasites, and immunosuppression. They also recommended that the EPA support additional research in advance of the registration review, avoid relying on industry-funded studies, and consider lowering the currently allowed maximum contaminant concentration, or phasing out atrazine altogether.

The Conservation Committee also reviewed and endorsed (on behalf of SSAR) a pre-publication copy of the second edition of *Habitat Management Guidelines for Amphibians and Reptiles of the Midwestern United States*, a technical publication produced by Midwest Partners in Amphibian and Reptile Conservation (PARC). Finally, during federal congressional committee meetings regarding deficit reduction in Fall of 2011, SSAR signed on to a "Teaming with Wildlife Coalition" letter urging preservation of funding for critical conservation, recreation, and historic preservation programs in 2012. Betsie thanks Priya Nanjappa, Carol Rizkalla, Chris Jenkins, Jason Rohr, Christine Bishop, and Rick Relyea for bringing issues to the attention of the committee and/or providing information to help them respond to various issues over the past year.

Joe Beatty (Chair, Dean Metter Award Committee) received 20 proposals this year and two winners were chosen. They are: Nicole Karres, an M.S. student in the Biology Department at Sonoma State University (whose thesis research deals with the diet and feeding ecology of the Western Pond Turtle, *Emys marmorata* in two urban habitats) and Dustin Owen, an undergraduate biology major at Ball State University, whose proposal was entitled, "Physiological impacts of roads on copperheads (*Agkistrodon contortrix*)." The Committee thought that both projects exemplified the kind of work that Dean Metter would have appreciated and enjoyed very much. In later discussions, the Board decided that, unless other funds become available, the budget line for the Metter Award should be capped at $1,000.

The 20th annual Seibert Awards Competition (Rafe Brown, Chair) was run at the 54th Annual Meeting of SSAR in Minneapolis, Minnesota. There were 38 eligible presentations. The Seibert Award winners for 2011 were (names of winners in bold): Systematics/Evolution: **Daniel Scantlebury**, University of Rochester, "Patterns of Adaptive Radiation in West Indian Dwarf Geckos (Sphaerodactylidae: *Sphaerodactylus*)." Ecology: **James Paterson**, Brad Steinberg, and Jacqueline Litzgus, Laurentian University, "Generally Specialized or Especially General? Habitat selection by Snapping Turtles (*Chelydra serpentina*)." Physiology/Morphology: **Angela Rivera**, Clemson University, "Evolution of Flapping in Turtles: A Comparative Examination of Forelimb Kinematics and Muscle Function across Three Lineages (Trionychidae, Carettochelyidae, Cheloniidae)." Conservation: **Jeanine Refsnider**, Fredric Janzen, Iowa State University, "Nest-site Choice in Response to Climate Change and Effects on Offspring Performance in a Turtle with Temperature-dependent Sex Determination." Awardees received a $200 check and a book from Chuck Crumly at University of California Press.

Honorable Mentions in the Seibert competition were: Systematics/Evolution: **Charles Linkem**, University of Kansas,

"Species Tree Despite Gene-Tree Incongruence in Large Datasets: The Phylogeny of the *Sphenomorphus* Group (Squamata: Scincidae)." Ecology: **Andrew M. Durso**, Stephen J. Mullin, Eastern Illinois University, "Interactions of Sex, Age and Behavior in Death-feigning Snakes (*Heterodon*)." Conservation: **Steven Price**, Robert Browne, Michael Dorcas, Davidson College, "Modeling the Effects of Urbanization on Salamander Abundances using a Before-After Control-Impact Design." **Yik-Hei Sung**, Nancy Karraker, Billy Hau, The University of Hong Kong, "Impacts of Illegal Trapping on Endangered Big-headed Turtles (*Platysternon megacephalum*) in Hong Kong."

The largest project of the Herpetology Education Committee (HEC) continues to be the Meritorious Teaching Award in Herpetology (MTAH), sponsored by The Herpetologists' League, the Society for the Study of Amphibians and Reptiles, and the American Society of Ichthyologists and Herpetologists.

In 2013, all remaining candidates for the MTAH plus any new nominations received during the year will be eligible for consideration for next year's MTAH, but in 2014, some of the earlier candidates will not be eligible according to the current guidelines. The HEC chair recommended that this stipulation of ineligibility be reconsidered so that clearly outstanding candidates continue to be eligible for consideration. The Board voted to support this recommendation.

The HEC received a letter of application from Shelby Miller as part of the SSAR Mentorship Program. All three herpetology societies had formerly agreed to collectively underwrite the registration fees for one pre-baccalaureate student and accompanying person per year. The HEC unanimously approved the application from Shelby Miller to the SSAR Mentorship Program to receive the funds for the K-12 student award to attend the Vancouver meeting.

Whit Gibbons is stepping down as chair of the HEC at the WCH and he thanked the several dedicated members of the HEC for their many contributions to herpetological education. Hinrich Kaiser volunteered to serve as chair of the HEC.

Kennedy Award Chair, Lynnette Sievert, announced that the winning paper for 2011 is by **Mizuki Takahashi** (coauthored with Yukiko Takahashi and Matthew Parris) "Rapid change in lifecycle polyphenism across a subspecies boundary of the eastern newt, *Notophthalmus viridescens*. *Journal of Herpetology* 45:379–384." Mizuki will receive a check for $200 or $400 worth of SSAR publications.

Kraig Adler, Chair of the Long Range Planning Committee (LRPC), reported that after its formation in Fall 2010, the LRPC submitted a series of recommendations to the SSAR Board regarding changes to *Herp. Review*. These recommendations were approved and rapidly implemented by editor Bob Hansen. At the JMIH in 2011, the Board approved the recommendation from the LRPC for an increase in membership dues and institutional subscriptions and the formation of a "senior member category." Despite some decrease in numbers of members and institutions, Kraig reports that our income from dues is currently up. Thus, the Board's decision to increase dues and subscriptions has been successful in increasing income, in order to cover the changes in *Herp. Review* and to help other society programs. Kraig warns however that we must not be complacent about the loss of some members and suggested that President Mendelson send a letter to all lapsed members and institutions to point out the many features recently added to a membership in SSAR and to tell them that we very much want them back in the society. Kraig reiterated his call for a vigorous membership drive with a sound plan, a solid budget, and a means of assessing success. The new membership brochure that Breck produced for distribution at WCH is a good start.

The LRPC found a proposal from Allen Press to co-publish *JHerp* unacceptable on philosophical and material grounds and voted 9 to 2 to decline the proposal as written. There were some features of the proposal that were interesting and the Board encouraged the *JHerp* co-editors to consider the costs of implementing some of them. The LRPC discussed a proposal to assume management of the existing on-line journal *Contemporary Herpetology*. Although the LRPC was sympathetic to the need for an online-only journal, they felt that seven existing publication series stretched the SSAR's budget and editorial capabilities to such an extent that it was not feasible to accept it. The LRPC unanimously recommended that SSAR decline the proposal and the Board agreed. (Subsequently, the Center for North American Herpetology has announced that it is assuming responsibility for *CH*.)

During the Fall of 2011, the LRPC considered three topics: SSAR Website, Future Meeting Sites, and the Society's International Status. Each of these topics was discussed by the committee via email, at an Open Meeting of the LRPC that was held at the Minneapolis meeting, and further by email during the Fall months. Eventually, the LRPC made two recommendations to the Board, both of which were approved. These are:

1. SSAR website.—There is a strong desire to make our website more user-friendly, to make it easier for officers and editors to post relevant information, and to maximize its use to promote the society and herpetology in general, both to our membership and to the general public. A subcommittee (Bob Hansen, chair; Breck Bartholomew, Raul Diaz) developed a plan, which was submitted to the full LRPC for discussion and vote (11 yes, 0 no, 1 abstained). This plan recommended a first-year budget of $10,000 with annual allocations of $3,000. The Board accepted the LRPC's recommendation. President Mendelson will now appoint a committee and a person to implement this initiative.

2. Future meeting sites.—SSAR has had a long tradition of annual meetings from its founding in 1958. We have used a variety of formats: SSAR (or OHS)-only, SSAR-HL, SSAR-HL-ASIH, and JMIH. Our last SSAR-only meeting was in 1996 and the last SSAR-HL meeting in 2001. Kansas State Conference Management Services began handling the JMIH in 2002. Because of size, these have been held in conference centers or in large hotels with conference facilities. This arrangement is (usually) convenient, but it comes at the cost of high hotel room rates, high fees for exhibitors (thus, few now attend), and the need to meet in busy downtown areas.

Historically, SSAR has met on university campuses (35 times), museums (6), and biological stations (twice), venues that are familiar to academics and where costs are more moderate (especially room rates, as at UBC this year). Many herpetologists have suggested to us that SSAR consider meeting on university campuses occasionally, even as a SSAR-alone event. Our current contract with JMIH states that we may opt out of any year's meeting on three years' notice.

The LRPC considered the general question of occasional herpers-only meetings. To make this a realistic discussion, with President Mendelson's permission Kraig Adler approached the University of Kansas (Rafe Brown, Linda Trueb, Bill Duellman) to see if they might be interested in hosting a meeting in 2014 or 2015. Their response was positive.

The LRPC voted in favor of occasional SSAR-only, on-campus meetings (i.e., once every 3–5 years, that is, once in the "lifetime"

of a graduate student). The committee did not vote specifically for KU, but this real possibility was known to them. The SSAR Board, however, took two votes: 1) to pursue SSAR-only meetings every 3–5 years [approved 10 yes, 3 no]; and 2) to pursue KU for a meeting in 2015 [9 yes, 3 no, 1 abstained].

Accordingly, Kraig has been working with Rafe, Linda, and Bill to put together a formal proposal. The meeting (30 July 30–3 August 2015) would be headquartered at the Kansas Union, where SSAR met in 1977 and 1996, and located immediately adjacent to the Museum of Natural History. The KU local committee consists of Rafe Brown (chair), Linda Trueb, Bill Duellman, Rich Glor, and some others. Rafe will formally invite PARC to co-sponsor this meeting, as a way to make conservation a main theme at that meeting and to develop new connections between SSAR and PARC (subsequently PARC accepted SSAR's invitation).

Rafe is planning for up to 500 participants. The Local Committee is planning a special program of events including some traditional and popular ones from SSAR meetings of yesteryear. Their main effort is to make this meeting enjoyable, both scientifically and personally, especially for our student members, and to bring back senior members who have not attended in a long time.

In his capacity as President, Joe Mendelson serves as SSAR representative on The Meeting Management and Planning Committee (MMPC). The Committee did not meet this past year (because WCH was responsible for planning the 2012 meeting), but did plan to meet during WCH. President Mendelson, and President-Elect Bob Aldridge will attend a planning meeting in Albuquerque in March 2013. Marty Crump will replace long-serving chair of the MMPC, Mo Donnelly. Upcoming JMIH meetings are:

2013 — Albuquerque, New Mexico

2014 — Chattanooga, Tennessee

2015 — Reno, Nevada

Ann Paterson (chair) reported that during 2011-2012, the Membership Committee voted to become less active while waiting to see the results of the many proposals that were presented at the 2011 board meeting. The Committee felt that it would be more helpful to see how other committees decided to respond to those than to continue to present more, especially as those proposals were based on considerable contemplation combined with the results of a substantial membership survey. A separate Mentorship Committee was formed to pursue mentorship activities specifically. The Membership Committee did accomplish the following: 1) designed a bookmark featuring mantellas by Tim Halliday and listing SSAR member benefits that was distributed with renewal notices in 2011; 2) continued to work on compiling a list of other herpetological societies (both in the U.S. and internationally); and 3) responded to concerns and comments from members and non-members as needed.

The number of members decreased slightly in 2012, which obviously concerns the Membership Committee. There are already 49 individuals taking advantage of the new Senior category. However, there are fewer individual memberships and fewer institutional memberships. The only membership categories showing increases were Associate memberships and Life memberships. While it is not unexpected to see a decrease in members following a dues increase, the Committee feels that it should work diligently to attempt to counteract this decrease over the next year. Marina Gerson will take over as chair of the Membership Committee and agreed to write a proposal for a Membership Drive that will be sent to the Board. Gad Perry reminded the Board of the large number of manuscripts he receives for publication in *JHerp* that are from overseas, and emphasized the need for the drive to be international in focus.

The Mentorship Committee was formed by President Mendelson as an *ad hoc* committee to create a program to help students new to the annual meeting navigate social and academic events, and to meet other students and faculty relevant to their interests. President Mendelson appointed Kristine Kaiser as chair of this committee, and Marion Preest and Andrew Durso to serve on the committee. A survey of the student membership suggested that graduate student mentors would be preferred to faculty mentors. The committee advertised the program on the society's website and Facebook page, the WCH meeting registration page, and in *Herp. Review*. Fifteen students, from high school age to advanced graduate student, applied to the program this year and all were accepted. The committee matched mentors to the mentees for the WCH based on research interests. Although the mentoring part of the program is intentionally not highly structured, the committee planned a meet-and-greet on the first night of the WCH for all mentors and mentees to meet face-to-face, and invited all mentees to the SSAR/HL Student Reception.

The Nominations Committee (Greg Watkins-Colwell, Chair) compiled a list of nominees (see below) for the positions of President-Elect, Treasurer, Secretary, Regular Board Member, and non-US Board Member. Kirsten Nicholson is stepping down as Treasurer and the Board gratefully thanked Kirsten for her service. President-Elect: Aaron Bauer, Geoff Smith; Treasurer: Ann Paterson; Secretary: Marion Preest; Board Member (Regular): Frank Burbrink, Richard Durtsche, Marina Gerson, Liza Hazard, Greg Watkins-Colwell; Board Member (non-US): Alison Cree, Carlos Navas, Hidetoshi Ota, Wolfgang Wüster.

Resolutions Chair, Robert Denton, reported that resolutions were presented at the SSAR Business Meeting in Minneapolis in 2011. These have been published in *Herp. Review*.

Chair of the Roger Conant Grants-in-Herpetology Committee, Josh Kapfer, received 87 proposals this past year. This is the largest number since at least 2001. Most applications were in the "Travel" and "Laboratory Research" categories. The winners each receive $500 and they are: Conservation: **Tyler D. Hoskins**, Miami University of Ohio; Education: **Jacob Ngwava Mueti** and **Beryl A. Bwong**, National Museums of Kenya; The Andrew H. Price Field Research Grant in Herpetology: **Jesse Delia**, Boston University; Laboratory Research: **Robert Literman**, Iowa State University; Travel: **Rebecca Tarvin**, The University of Texas at Austin; International: **Stefano Canessa**, University of Melbourne, Australia.

Josh reports that the deadline for proposal submission remains December 15th, and he attempts to have reviewers secured by mid-January of the following year. Two reviewers were secured per grant category this year, but several were late in returning comments and rankings. This resulted in the decisions reaching all applicants later than normal. For this year, it was suggested that, based on monetary donations, the Field Category be renamed "*The Andrew H. Price Field Research Grant In Herpetology*." The change was adopted for 2012. In grateful recognition of Andy's long service and commitment to the Society, the Board indicated its willingness to continue with this name as long as funds are available (currently for the next two years).

Brian Crother, Chair of the Standard English and Scientific Names Committee, indicated that the 7th edition of the Standard English and Scientific Names List will be included in meeting bags at WCH. The introduction was expanded to provide a brief history of names lists for North American amphibians and

reptiles as well as provide rules for English name formation. The list of sanctioning societies for the 7th edition was expanded to include the SSAR, HL, ASIH, the Canadian Association of Herpetology, the Canadian Amphibian and Reptile Conservation Network, and PARC. A special French names list was produced for the WCH. David Green chaired the committee that produced the list. The online edition of the names list will continue and may be expanded. With the CNAH dropping its involvement in names, they have offered to be an additional outlet for the SSAR, HL, ASIH list.

No report was received from the Student Participation Committee. A suggestion was made to hold a workshop at the 2013 JMIH focusing on how to move student theses from dissertation to publication.

The first annual SSAR Student Poster Awards were presented at the 54th Annual Meeting of the SSAR in Minneapolis, Minnesota. Twenty eligible students participated in the competition. All awardees received a check for US $100 and a book award from Chuck Crumly at University of California Press. The winners were: Evolution, Genetics, & Systematics: **Anthony Geneva**, University of Rochester, "A Multi-locus Molecular Phylogeny of Distichoid Anoles;" Ecology, Natural History, Distribution, & Behavior: **Beth Pettitt**, University of Minnesota, "Oviposition and Tadpole-rearing Site Selection of a Phytotelm-breeding Frog, *Anomaloglossus beebei*;" Physiology & Morphology: **Mingna Zhuang**, University of California, Berkeley, "Comparative Gliding Performance of *Anolis carolinensis* and *Anolis sagrei*."

Vinny Farallo and Mike Jorgensen continue as co-chairs of the Student Travel Awards Committee. They reported that $1,763 was raised by the Silent Auction at the 2011 JMIH. There were 51 applications for the student travel award in 2012 and 10 winners were selected randomly. In an attempt to increase donations, a notice requesting donations for the silent auction was published in the March issue of *Herp. Review* and on the WCH website. A major goal this year (and in future years) was to increase auction donations. Vinny Farallo contacted 10 herpetologists and five publishers in May to solicit donations for the silent auction. Vinny is also keeping a detailed list of all people/publishers contacted to help avoid repeat solicitations in future years. They indicated some success from advertising on the WCH website and *Herp. Review*.

Webmaster Raul Diaz reported that activity on the website involved upkeep with common names and edits to pages. According to Election Officer Dan Noble, no election was held in 2011.

Coordinator of the Live Auction Committee, Greg Watkins-Colwell reported that, in 2011 the ASIH joined SSAR and HL for the Live Auction which featured items from the Ernie Liner collection. Proceeds from this auction, after all expenses are paid, are to be used for establishing a fund in each of the three societies for "up and coming herpetologists" as per Ernie's will. Auctioneers for 2011 were Brad Moon, John Moriarty, Steve Mullin and Aaron Bauer. Students assisting the live auction were Heather Heinz, Jolene Rearick, Alicia Kennedy, Brittany Barker, and Jenny Gubler. Efforts were made to include as many different auctioneers (with different auctioning styles) as possible and to rely upon students who had not helped with the auction in the past. The latter was facilitated by announcing at the student social the need for student volunteers. The auction had a Mardi Gras theme with each registered bidder getting a string of beads and a drink ticket that could be used for soft drink, beer, wine, or a hurricane. Through the evening a Powerpoint presentation ran on the screens between auction lots and featured photos from throughout Ernie Liner's life (thanks to Joe Mendelson). Each winning bid received another set of beads and sometimes coins. This served as a game whereby the person at the end of the night who had the most beads (and coins) would win a one-year membership to each of the three societies. The winner was Shelby Miller. The live auction made $4,766 which approximately equaled the costs. In addition to the live auction items, donations were actively sought during the auction via the "sale" of Mardi Gras beads. At a side table during the auction we sold refrigerator magnets and toys. These two activities brought in an additional $557 to be split three ways. Although the income from the auction was low due to the overhead cost of the Mardi Gras theme and splitting profits three ways, the notion of a theme-based auction was a success. Participation from the membership was high and the event was fun. The Live Auction Committee is exploring other ways to inject fun into the auction. Ideas include games and live music. The Committee is exploring the option of a "cover charge."

Representative to AIBS and BioOne, Al Savitzky, reported that AIBS continues to re-examine its role as an umbrella organization, representing about 160 member societies and organizations (MSOs), as well as its several thousand individual members. AIBS has been involved for about two years in an intensive strategic planning process, and the results of that process are expected to be announced later this year. The basic goal of the strategic planning process is to determine what the most effective role can be for such an umbrella organization, and how the Institute can best serve its member organizations and the discipline of biology in general. Toward that end, AIBS extensively revised both its Constitution and Bylaws during the past year, to ensure that it has the flexibility to respond more quickly to the rapidly changing landscape of professional organizations. The AIBS leadership continues to include a large number of biologists with research interests in ectothermal vertebrates, including Vice President James Collins and Board members James Hanken, Joseph Travis, and Al Savitzky.

Several important changes have already taken place in the organization, including the discontinuation of the formal annual meeting of the society. The AIBS Council, which previously met in association with the annual meeting, met this year in association with the Institute's spring meeting of its Board of Directors. Some representatives participated via teleconferencing. The trend toward remote participation is likely to increase in the future.

AIBS continues to concentrate a great deal of effort and staff time in two areas, public policy and education. These two realms of AIBS activity, together with the historic commitment of the Institute to organismal biology and ecology and the representation it provides in Washington, continue to offer substantial benefits to its member organizations. Members of MSOs, such as this society, are encouraged to consider joining the AIBS Legislative Action Center (http://capwiz.com/aibs/home/), which provides a simple way to stay informed on important congressional action regarding biodiversity and support for scientific and funding agencies, as well as affording a direct means to contact members' national legislators.

The nonprofit electronic publishing consortium BioOne continues to serve many society publishers of journals in organismal biology, ecology, and other fields. Increasingly these have included journals published overseas, either through direct electronic publication by BioOne (e.g., *South American Journal of Herpetology*) or through partnership with UniBio in Japan (e.g., *Current Herpetology*). For the first time, Al Savitzky was unable to attend the annual Publishers and Partners Meeting of BioOne, held in

May 2012 (http://www.bioone.org/page/about/meetings/past). In addition to the annual update on the status of BioOne, this year's presentations included discussions of rapidly evolving fair use policy in digital publications, open-access publishing, an evaluation of BioOne's new mobile app, and TEEAL (a program from Cornell University for delivering agricultural journal content offline to developing countries).

BioOne Executive Director Susan Skomal reported that, in the 11 years since the launch of the original BioOne collection (BioOne.1, with 89 titles), the collection has returned $19.96 million to its member publishers. BioOne's annual royalties to publishers continue to increase, and its price per page (to subscribing libraries) has dropped. Five years ago BioOne launched a second collection of journals, BioOne.2 (with 66 titles), designed to serve additional nonprofit publishers while not eroding the financial benefits to original consortium members. That second collection has shown even greater growth in recent years and has continued BioOne's record of success. Together with BioOne's 12 open access titles, the three BioOne collections now include 167 titles from 126 publishers. In 2011 BioOne published more than 97,000 articles totaling over 800,000 pages, and generated more than 27.6 million hits, an increase of 10.7% over 2010.

The issue of open access (OA) publishing was discussed by Alan Kahan of the Entomological Society of America, which publishes several journals with a variety of OA options. One journal is entirely OA, whereas others allow all authors to post their articles online at no charge after an embargo of two years (or immediately, if an OA fee is paid). Kahan referred to a study of articles published through Highwire Press that found that, although OA articles received more downloads and a wider audience in the first year after publication, the number of citations was no different from non-OA articles after three years. It is not yet clear whether OA substantially affects article use by other scientists, but it does make the material more readily available to a broad public audience. A recent development is the appearance of "predatory OA journals," which charge authors to publish articles online but have low scholarly standards and, in some cases, no peer review whatever.

Kevin Meinershagen of Allen Press discussed the new BioOne mobile app, which launched in November 2011. Mobile internet usage is projected to exceed desktop internet usage by 2014, and the number of individuals with a web-capable phone increased by 39% last year, so the mobile market for bibliographic information may be quite large. Although organized differently than the full BioOne site, the mobile app is very effective on such devices, and members are encouraged to consider using the free mobile app from BioOne.

SSAR Symposium Coordinator, Richard Durtsche, received two proposals in 2011. The first proposal entitled "Impact of Energy Development on Amphibians and Reptiles in North America" was submitted by Terry Riley as lead organizer, with Deanna H. Olson, Alvin R. Breisch, and Priya Nanjappa as a co-chairs. The purpose of this symposium is to examine the potential effects of traditional and renewable energy developments on amphibians and reptiles in North America and to identify appropriate research needs and management recommendations. While there have been several recent studies on the impacts of energy developments on wildlife (bats, Greater Sage-grouse, Lesser Prairie-chicken, Mule Deer, Pronghorn, and songbirds), few studies have focused on the impacts these developments are having on amphibians, reptiles, or their habitats. Reliable baseline data are needed on amphibian and reptile population densities and distributions over large portions of North America before the effects of energy development can be examined.

The second proposal, "A Global Partnership for the Ecology and Conservation of New World Vipers," was submitted by Christopher L. Jenkins as lead organizer, with Heidi Hall and Douglas L. Hotle as a co-organizers. In light of the threatened or endangered status of many viper species and their generally misunderstood and underappreciated value as animals, the Orianne Society has partnered with the IUCN to form the Viper Specialist Group (VSG). This symposium will kick off the opening meeting of the VSG with presentations by the world's experts in viper ecology and conservation. Thus, the symposium will provide a platform for the world's leaders in viper biology to present the most up-to-date science on vipers and provide the opportunity for the broader herpetological community to become involved with the VSG. In addition to building relationships among several societies, the symposium will reinforce the collaborative relationship among nonprofit organizations, academics, and zoos, and lead to stronger conservation initiatives.

Both symposium proposals were sent out for external review with two reviewers each. The reviews and proposals were submitted to the SSAR Board for consideration of sponsorship.

New Business.—A proposal was received from University of Kansas to host the annual meeting in 2015 (30 July–3 August). The Local Committee would consist of Rafe Brown (Chair), William Duellman, Linda Trueb, and Rich Glor, who would work closely with KU's Center for Professional Development (Gina Cregg, director). KU has hosted two successful SSAR meetings previously (1977 and 1996) and regularly hosts professional meetings. The proposal was discussed, voted on, and accepted by the Board.

Several issues were raised by the *JHerp* co-Editors (Erin Muths and Gad Perry).

1) *Page charges.*— The Board previously asked Erin and Gad to develop a page charge policy for its consideration. Discussions of their proposal at the 2011 JMIH stalled, and ongoing email-based deliberations since then have mostly been unfruitful (the one exception is the agreement that the Publications Secretary will take on the job of handling page charges and copyright releases). Erin and Gad continually receive inquiries about page charges. At the request of President Mendelson, they provided a detailed proposal in which they suggested a graduated payment structure, where regular members are asked to pay $50/page, student members and retired persons are asked to pay $25/page, and non-members are charged $150/page. An average non-member would pay about $1000/paper, but would only pay about $450 (membership included) if they chose membership. As the current policy does not require payment or even an explicit waiver, Erin and Gad suspect that most students currently provide no page charges. Given a 20% compliance rate, which seems quite feasible now that Breck's office will be handling page charges, they expect the greater payment coming in from non-members to help offset any income lost from giving members a price break. They suggested that the Publications Secretary be authorized to provide to members waivers in common situations (students, developing countries), be instructed to be less lenient with non-members (while recommending membership), and consult with the Editors on special cases such as invited papers. Hopefully, Breck's office can provide the co-Editors with a breakdown of income in 2013 which will allow them to reevaluate these numbers and update the Board.

The Board discussed the obvious need for a clear, consistent policy that encourages membership in SSAR and submissions to

our journals. Concerns were expressed that authors may choose to publish in journals without page charges if we adopt a policy that includes charges. After considerable discussion, it was recommended that no page charges be assessed as long as the author (or at least one of the authors if more than one) is a member in good standing of SSAR. However, if funding allows, members are encouraged to assist by contributing to page charges. If the author (or none of the coauthors) of the manuscript is not a member, he/she will be given the option to become a member. If they choose to not join the Society, they will be asked to pay the current page charge rate. They will also have the option of requesting a waiver of charges from the Publications Secretary. This information will be published on the website in *Instructions to Authors*. The Board voted to adopt this policy.

2) *Electronic publishing*.—Journals are increasingly going wholly or optionally digital. According to the LRPC, about 10% of our membership has chosen the digital-only option, and this is likely to grow. Erin and Gad see this as a positive move, but feel that greater electronic presence is needed. For example, they are increasingly being asked about digital features such as posting of accepted papers on a journal web site prior to publication. They acknowledge and appreciate the efforts of the current (volunteer) webmaster. However, the Journal web site and the available capabilities are likely to often be the first (and perhaps only) contact that nonmembers have with the Society. They therefore feel that we are jeopardizing the standing of both the Journal and the Society by not utilizing a full time, professional service. If services such as online early publication are not available, or if details such as *Instructions to Authors* are out of date or poorly formatted for some screens, then potential members are likely to go elsewhere.

In 2011, the Board rejected the Allen Press (AP) co-publishing proposal, but authorized Erin and Gad to further investigate the costs of implementing especially attractive features of the proposal and bring them back to the Board for further discussion. Having a professional web-presence is the highest priority item. Although the Board has approved $10,000 for revamping the SSAR web page and $3,000/yr for maintenance after that, this is not going to address the need for seamless integration and full-time technical support. The current proposal for this from AP would utilize the AP Pinnacle platform, require a one-time $3,000 setup fee, and entail an annual cost of $14,120 which would cover all preparation and hosting expenses.

The Board considered this issue. There was discussion of on-line pre-publication of papers on taxonomy (this would not happen) and concerns regarding too many links (because of a need for regular updates) and a potential loss of "branding." The Board voted to accept the proposal from AP.

2) *Difficulties in obtaining qualified AEs and reviewers*.—Erin and Gad regard this as currently the biggest challenge to a more rapid manuscript handling process. Given the increasing shift of academic institutions to a for-profit managerial style, they expect this problem to get worse and negatively impact the quality and timeliness of reviews. Recruiting capable new AEs, who spend considerably more time than reviewers in the service of the journal, remains extremely difficult. Many leading journals provide AEs (and some also to reviewers) token recognition for their services. The past suggestion to provide AEs with free membership was an attempt to partially address this, but was rejected by the Board in both 2010 and 2011. At the instigation of Erin and Gad, names of Editors and AEs for the *Journal of Herpetology* (and other herpetological journals) are printed in the WCH program (at no cost to SSAR), but they do not feel that this small step is sufficient. They would appreciate the Board reconsidering token recognition, which they envision to be granted only to those AEs who have served for over a year and completed their reviews in a timely manner.

A wide-ranging discussion followed. It was suggested that AEs who serve a multi-year term be granted the honorific "fellow," that donations be solicited to provide small grants to AEs, that officers of the society serve as reviewers or AEs after their term as an officer is over, that the Editorial Board be utilized more, that presidents from a number of societies (including SSAR) consider writing a policy piece for publication in a major journal (e.g., Science) addressing the vital importance of editorial and reviewing service to our field.

In 2011, the LRPC, SSAR Board, and President Mendelson informally initiated a new series of "Lifetime Achievement Awards" for select colleagues who have contributed significantly to the Society and/or the field of herpetology during their careers. Kraig Adler and his production assistant Tim Perry produced attractive formal documents and they were signed by available board members and senior officers/editors. Several more worthy recipients were informally proposed in 2012 and similar awards were produced and presented. The achievement awards evidently have become a popular and requested commodity, yet SSAR has no guidelines to govern if, when, or how they are to be awarded. In order to maintain their professional and personal value, they should be administered according to agreed standards and perhaps limited in number each year, so as not to "flood the market" and thereby diminish their perceived value. President Mendelson submitted a proposal that these awards shall be renamed as the "SSAR Presidential Award for Lifetime Achievement in Herpetology" and shall normally be limited to three awards per calendar year. There will be no committee, but rather nominations may be made by any active Board member, officer, or primary editor directly to the President. The President/Secretary will call for an electronic vote from the Board. If approved by majority vote, the President (alone) will sign the award and deliver it to the recipient, and make the announcement at the annual Business Meeting. The Board voted to approve this proposal.

In the 1980s, David Dennis, Eric Juterbock, and Kraig Adler produced four different audio-visual shows for use at SSAR, SSAR/HL, World Congress, and other meetings in US, Canada, and the UK. SSAR commissioned them. They seemed to be popular because the auditorium was always full and many people came back year after year to see them again. These have not been shown in several years because the technology is out of date (six slide projectors coordinated by an ancient computer) and not of high digital quality. Kraig suggested to the Board that SSAR may wish to commission a new, updated generation of these shows in digital format that would be much easier to show and even to export overseas to herp meetings to advertise SSAR. All photographs would have to be made digitally (the existing photos are faded), which will require a great deal of fieldwork, scanning originals, etc. If SSAR meets in Lawrence in 2015, these shows would be a magnet to draw an audience. They were especially popular among students. The Board voted unanimously to provide funding to partially cover the costs to re-do the shows.

Josh Kapfer (Chair, Grants-in-Herpetology) was contacted by an officer from another society with a question regarding liability insurance for our student research grants. The Board discussed this issue and decided that we should request that students sign a liability waiver when they submit proposals to our various

funding Committees. After the WCH, Josh produced a waiver form and this is now available on the website.

The future of the CAAR series was discussed. In 2011, *CAAR* Editor Andy Price reported that the series was languishing primarily as a result of lack of submitted manuscripts. This, coupled with lengthy review and editorial returns, resulted in an intermittent publication schedule. More generally, the hard-print non-updateable format became outdated and was not engendering much excitement, nor perhaps even much current use. President Mendelson appointed an informal committee to begin discussions for the future of the series. The members of this committee generally agree that the series is valuable in its original concept and propose that SSAR continue the series, but in a more affordable (pdf/online) format and also one that permits updates, and allows SSAR to exercise quality control over the product bearing our name. For taxa not yet covered in CAAR series, volunteer authors will produce CAAR accounts, which will be edited/reviewed per our usual model. For CAAR accounts that are now outdated, we will solicit updated versions which would include in a single pdf both the original (outdated) account, plus formatted addendum sheet(s) that include all literature and dot localities appearing since the original account was produced. This way both the original author and the update author would get credit. The citation could be something like "Conant and Siler 1970/2012."

CAAR accounts will become electronic pdf publications distributed online only. They will be available *gratis* on Zen Scientist to the entire membership. E-mail announcements to the membership should accompany the appearance of each new account, and once per year, *Herp. Review* should publish a list of the accounts appearing in the last calendar year. All parties should be working to remind our colleagues that these accounts are time-consuming to author, are of exceptional value to our field, and do constitute a peer-reviewed publication. Graduate students should be explicitly encouraged to author accounts or updates of their focal taxa, as they more than anybody will know the most recent relevant literature. Travis LaDuc and Chris Bell agreed to take over as co-Editors of CAAR and offered to develop a plan for the future.

SSAR received a request from Henry Mushinsky (member JMIH LRPC) that we initiate a discussion regarding what we want the future of our societies to look like. Henry asked us to consider the following questions: 1) Is there interest in uniting our societies under an umbrella society? 2) If so, what model do we want to use? Many are familiar with SICB, their divisions include animal behavior, ecology and evolution, comparative biomechanics, comparative morphology, phylogenetics and comparative biology and so forth. At our JMIH we use many of the same divisions used by SICB when we are preparing the academic program, i.e., fish ecology, herp systematics, shark behavior, and so forth.

Specifically, Henry was asking for some guidance on whether SSAR though the JMIH LRPC should continue to think along these lines. The Board discussed the issue of an umbrella society for SSAR, ASIH, HL, etc., and what such a society would look like and be responsible for. A shared treasurer and shared editors have been suggested. Benefits could include cost-savings and streamlining. Concern was expressed regarding a potential loss of identity and institutional history and a sense that the various societies might be heading in different directions. There was a consensus among the Board that, although not willing to commit to anything definite, discussions regarding an umbrella society should continue and we would be interested in seeing what ideas were developed.

FIG. 21. Joe Mendelson, nearing the end of his two-year term as SSAR President, passing the gavel to President-Elect Bob Aldridge.

The Editors of *Herp. Review* and *JHerp* received a proposal from Allen Press that would increase the flexibility for using color in *JHerp* without heavy financial impact and at the same time bringing down the overall costs for both journals. All Editors were in favor of signing a contract with AP and the Board supported this.

President Mendelson received a request from an author of a manuscript submitted to *Herp. Review* that the Society endorse a resolution regarding taxonomic practice. Because this manuscript is still being reviewed, President Mendelson thought that a vote regarding the resolution was premature and unnecessary. The Board agreed.

A balanced budget for 2012 of $304,440 was approved by the Board and the meeting was adjourned at 1551 h.

SSAR Business Meeting

The annual SSAR Business Meeting was called to order by President Mendelson (1806 h on 11 August 2012). Twenty-two members of SSAR were present. Joe then introduced Judit Vörös who made an announcement about the European Congress of Herpetology to be held in Veszprém, Hungary, during 22–27 August 2013. Officers, Editors, and Committee Chairs who were at the Business Meeting introduced themselves to the other attendees and gave brief summaries of their Annual Reports and relevant information from the Board Meeting. There was some discussion of the Board's acceptance of the invitation from KU to host the 2015 SSAR Annual Meeting.

SSAR "Presidential Awards for Lifetime Achievement in Herpetology" were presented to Chuck Crumly, Ronald Javitch, and Marion Preest. Winners of the 2012 Travel, Seibert, and Student Poster awards were announced (Figs. 19, 20). As is traditional, outgoing President Mendelson passed the SSAR gavel to President-elect Bob Aldridge (Fig. 21). The meeting was adjourned at 1930 h.

—Respectfully submitted by Marion Preest, SSAR Secretary

NEWSNOTES

IHS Grants Available

The International Herpetological Symposium has established a grant program to provide financial assistance to individuals or organizations conducting herpetological research, conservation, and education. Proposals are accepted January through May of each year and grants are awarded in August. Grants are in the amount of up to US $500 and will be awarded to applicants whose projects represent a significant contribution to herpetoculture in one of the following categories: herpetological natural history, herpetological conservation biology, captive propagation, or herpetological education. For details on the application process, please visit the IHS website at <http://internationalherpetologicalsymposium.com/grant.html>

Amphibian Academy: Serving Amphibians
Developing Amphibian Conservation Expertise

We are pleased to announce a new capacity building program with a novel and holistic approach to amphibian conservation training for both *in-situ* and *ex-situ* program development. This new program is called *Amphibian Academy*: a broad perspective training opportunity that will benefit people from diverse backgrounds who desire to help save amphibians. A key difference between this effort and earlier endeavors is that the emphasis is on the individual student so that graduates will be poised to address the needs of threatened amphibians. Our mission is simple: train amphibian conservation biologists so that they can best *Serve Amphibians*.

The *Amphibian Academy* has been developed under the umbrella of the Amphibian Ark and the Toledo Zoological Society. It will be a week-long course with robust conservation emphases. The school is scheduled for 20–28 April 2013 at the Toledo Zoo, Toledo, Ohio, USA. The amphibian conservation and breeding programs at the Toledo Zoo are internationally known and the collection is extremely diverse—an ideal environment for training amphibian conservationists. Local field opportunities will be utilized for teaching purposes. Centrally located, Toledo is a friendly city with reasonably priced accommodations and food. Costs to attend will not be excessive.

The course includes lectures, hands-on practical exercises, and fieldwork. Most of all there will be ample opportunities for students to be personally mentored by globally recognized and successful amphibian conservationists to help them address their specific program's focus and needs. The students can rely on the faculty members to remain as their mentors and professional contacts throughout their careers. The hands-on activities are designed for students to "learn by doing" in small groups with an instructor, thus providing an optimal learning opportunity. The faculty for the course includes leaders in the fields of amphibian husbandry, medicine, research, reintroduction, and conservation. As amphibian decline knows no borders and is a significant global concern, we invite a diverse group of students from all countries. The vision for this training course is to *Serve Amphibians*. If this motto is in alignment with your conservation interests, this course will provide you with a unique opportunity to develop the appropriate skills for making a difference. Some scholarship opportunities will be available for deserving individuals with limited resources. There will also be a few short-term internships available to qualified students after the course. Registration will be open in October 2012. Tuition costs US $750 and the process for obtaining financial support and internship opportunities will be announced shortly.

For registration information and process, contact AArk Education Officer, Rachel Rommel (Rachel@AmphibianArk.org), or

Ron Gagliardo (Ron@AmphibianArk.org) and Andy Odum (RAOdum@aol.com).

Sabin Award for Amphibian Conservation

Since 2007 Conservation International and the IUCN Amphibian Specialist Group have been offering the Sabin Award for Amphibian Conservation. Recipients have included Luis Coloma (Ecuador), Franco Andreone (Italy), Jonh Jairo Mueses Cisneros (Colombia), SD Biju (India), Herilala Randriamahazo (Madagascar), Alonso Quevedo (Colombia), and the 2012 recipient Karen Lips (USA). The award recognizes true leaders in local and global research and conservation efforts toward addressing the ongoing demise of the world's amphibians. The award is sponsored by Andrew Sabin, a conservationist and philanthropist whose efforts and generosity are direct contributions toward global conservation efforts, including significant contributions toward amphibians. SSAR greatly appreciates Andrew Sabin's vision and efforts and extends congratulations to the winners of this award.

New Brazilian Journal

The Sociedade Brasileira de Herpetologia (Brazilian Herpetological Society) has launched a new open access electronic-only journal, *Herpetologia Brasileira*. The journal is published in Portuguese and is under the general editorship of Taran Grant and Marcio Martins. The journal may be accessed at: http://www.sbherpetologia.org.br/herpbras/index.html.

MEETINGS

Meetings Calendar

Meeting announcement information should be sent directly to the Editor (HerpReview@gmail.com) well in advance of the event.

10–11 January 2013—California/Nevada Amphibian Populations Task Force 2013 Meeting, Humboldt State University, Arcata, California, USA. Information: Dr. David Bradford (dbradfo@herpconbio.org)

21–23 January 2013—3rd International Symposium on Agamid Lizards (DeAgamis 3), Melbourne Museum, Melbourne, Australia. Information: Dr. Jane Melville (jmelv@museum.vic.gov.au)

29 January–1 February 2013—37th Meeting of the Australian Society of Herpetologists, Point Wolstoncroft, New South Wales, Australia. Information: http://www.australiansocietyofherpetologists.org/

2–8 February 2013—33rd Annual Symposium on Sea Turtle Biology and Conservation; together with Terrapin, Tortoise & Freshwater Turtle Meeting, Baltimore, Maryland, USA. Information: http://iconferences.seaturtle.org/

22–23 March 2013—4th Box Turtle Conservation Workshop, North Carolina Zoological Park, Asheboro, North Carolina, USA. Information: www.boxturtleconservation.org

20–23 May 2013—World Crocodile Conference, 22nd Working Meeting of the Crocodile Specialist Group IUCN-SSC, Colombo, Sri Lanka. Information: www.csgsrilanka.com

10–15 July 2013—Joint Meeting of Ichthyologists and Herpetologists (SSAR, HL, ASIH), Albuquerque, New Mexico, USA. Information: http://www.dce.k-state.edu/conf/jointmeeting/

21–25 July 2013—26th International Congress for Conservation Biology, Baltimore, Maryland, USA. Information: http://www.conbio.org/mini-sites/iccb-2013

31 July–3 August 2013—36th International Herpetological Symposium, New Orleans, Louisiana, USA. Information: http://internationalherpetologicalsymposium.com/index.html

22–27 August 2013—SHE 17th European Congress of Herpetology, Veszprém, Hungary. Information: http://seh2013.org/

3–6 October 2013—4th Biology of Vipers Conference, Struga, FYR Macedonia. Information: www.shdmr.org/vipers

CURRENT RESEARCH

The purpose of Current Research is to present brief summaries and citations for selected papers from journals other than those published by the American Society of Ichthyologists and Herpetologists, The Herpetologists' League, and the Society for the Study of Amphibians and Reptiles. Limited space prohibits comprehensive coverage of the literature, but an effort will be made to cover a variety of taxa and topics. To ensure that the coverage is as broad and current as possible, authors are invited to send reprints to the Current Research section editors, Beck Wehrle or Ben Lowe; e-mail addresses may be found on the inside front cover.

A listing of current contents of various herpetological journals and other publications is available online. Go to: http://www.herplit.com and click on "Current Herpetological Contents."

Night Lizards Aggregate to Stay Warm, But Climate Change May Affect Behavior

There is little known about why or how sociality originates, though various studies of taxa from across Animalia suggest that delayed juvenile dispersal is a common path to sociality. Social living is thought to confer fitness benefits, but this is difficult to measure in complex social systems. The authors of this study were able to collect genotypic and physical fitness data on aggregating and solitary individuals of the Desert Night Lizard (*Xantusia vigilis*) through marking and recapturing 2,332 lizards in 441 social groups. In winter, approximately two-thirds of these lizards aggregate in groups of 2–20, usually with kin. Using microsatellite data to infer parentage, the authors compared fitness across solitary and grouping lizards, finding that males who were solitary in the winter did not produce offspring the next summer. Conversely, some grouping males produced offspring with multiple females. Aggregated female lizards had an increased survival rate and aggregated females and juveniles were significantly fatter than their solitary counterparts. The frequency of aggregation was found to be strongly inversely correlated with temperature. Additionally, the authors found that groups of lizards lost heat more slowly than solitary lizards, including experimentally isolated individuals. As huddling changes the surface area to volume ratio, this is not surprising, and, indeed, the effect scaled with mass and therefore affected small juveniles the most. The average difference in time to temperature equilibrium between solitary and grouping lizards was 6.5 hours, greatly minimizing the amount of time aggregations experienced the coldest temperatures relative to solitary individuals. Since this social behavior has thermal consequences, the authors considered four climate change models to determine how aggregations might be affected in the future. They modeled monthly aggregation levels from 1950 to 2099, finding a decrease in number of groups and duration of grouping through time. By 2099, the aggregation rate is expected to decrease by at least 20% and up to 50% of the modeled grouping rate from 1950. Social aggregation provides fitness benefits to adults and juveniles in the form of thermal buffering and decreasing metabolic costs, but may also allow for reproductive benefits to males such as through mate guarding. This study is important in testing the benefits of social behavior, as well as acknowledging the effect of environmental conditions.

Review of Poison Sequestering Amphibians and Reptiles Suggests Under-documentation

Toxin sequestering is rarely documented in tetrapods. Though it is not uncommon for compounds to accumulate in organism's tissues, the authors of this review paper note that this is not by itself sequestering for chemical defense. Defining sequestration as the novel evolution of poison retention that results in a selective advantage, they review the known cases in amphibians and reptiles. Based on morphological and physiological correlations, the authors suspect that the true diversity is much higher than currently known. In their examples, the authors identified the following prey classes that if included in diet, may indicate a tetrapod species is sequestering toxins for chemical defense: toxic arthropods, toxic mollusks, and toxic amphibians. Poison sequestering has been identified in five frog taxa: Dendrobatidae, Mantellidae, *Melanophryniscus*, *Pseudophryne*, and *Eleutherodactylus*. In these taxa, defensive toxins are obtained from eating poisonous arthropods. These frogs are also small, brightly colored, and generally at risk for predation from visual predators. Of interest is whether Dendrobatidae and *Melanophryniscus* independently evolved this trait or if it was retained from a common ancestor and lost in other descendents (e.g., the remainder of Bufonidae; determination awaits clarification of evolutionary relationships among the major hyloid clades). Other anurans, some plethodontids, and three species of caecilians are identified as candidates for sequestering chemical defenses. Among reptiles, scolecophidians and a lineage of arthropod-eating geckos, *Liolaemus monticola*, are potential poison sequesterers. Some snakes that specialize on eating mollusks also exhibit static defensive behavior (e.g., death feigning) or mimicry of known noxious prey (e.g., toxic millipedes), encouraging further investigation of their toxicity. Three species of garter snake (*Thamnophis*) sequester tetrodotoxin in their livers from consuming newts in the genus *Taricha*. The toxicity of *Taricha* and the tolerance of the snakes to tetrodotoxin covary geographically; populations of snakes that consume large quantities of newts have also been found to have aposematic coloration and a decreased flee response. The tetrodotoxin in *Thamnophis* livers can be lethal to avian or mammalian predators and garter snakes have been found to survive with a partial organ. The natricine snake *Rhabdophis tigrinus* stores bufadienolides in its nuchal glands, even passing along these compounds intergenerationally to neonates. With this sequestration, *R. tigrinus* has also developed behavior to direct their glands at oncoming predators. Other *Rhabodophis* and Xenodontini snakes are likely also using sequestered chemical defense. This review urges greater investigation of this field of research and suggests toxin sequestration in herpetofauna as a more common phenomenon than previously thought.

Facultative Parthenogenesis Found in a Garter Snake and Two Wild Pitvipers

Facultative parthenogenesis is rare in vertebrates, but has recently started being documented in sharks, birds, varanids, and snakes. The following two studies use microsatellite analyses to identify instances of parthenogenesis in otherwise sexually reproducing snake species and add support to the claim that facultative parthenogenesis might serve as an alternative reproductive strategy. Reynolds and colleagues[1] observed parthenogenesis in a wild-caught Checkered Garter Snake (*Thamnophis marcianus*) reared in captivity. The female was very young at isolation from other snakes. During her lifetime, she produced five litters that included three viable offspring, 11 stillborns, and numerous yolked ova. Blood, liver, muscle tissue, and shed skin were collected from the female and nine of her progeny to use for genetic analyses. Thirty microsatellite loci were identified and developed for comparison. Of these, 18 microsatellites produced clear results, and five were maternally heterozygous. In the young, differential homozygosity was observed at four microsatellite loci, and at one locus four offspring had identical genotypes to their mother. There was no evidence of any paternal genes, supporting this as an example of parthenogenesis and not sperm storage. Additionally, this is in line with the assumptions about the female's reproductive history. All three of the sexed offspring were male, as is expected with parthenogenesis in ZW organisms (where females are the heterogametic sex). These offspring developed normal looking hemipenes, suggesting that they were reproductively viable, though histological analyses of the testes were inconclusive to the presence of spermatozoa. Similar instances of facultative parthenogenesis have been confirmed in other *Thamnophis* species, but instances of successive virgin births confirmed via molecular data are few.

While facultative parthenogenesis has been documented in captive vertebrates, Booth and colleagues[2] report on the first known cases in the wild. The authors collected litters from 22 wild Copperhead snakes (*Agkistrodon contortrix*) and 37 wild Cottonmouths (*A. piscivorous*). Pregnant snakes gave birth in captivity and two litters were identified as being possibly parthenogenesis due to (a) production of single male offspring, and (b) multiple yolked ova (characteristics seen in previously confirmed parthenogenic squamate litters). These two litters were analyzed at seven (*A. contortrix*) or eight (*A. piscivorous*) microsatellite loci. Homozygosity for one of the maternal alleles was observed for all offspring. These genotypes were not found outside the mothers and their progeny. Inbreeding in the wild population was small and the calculated probability of a male providing an identical allele was incredibly small. The young were healthy at release. This study shows that facultative parthenogenesis is not just a captive phenomenon. Together these two studies suggest that facultative parthenogenesis may not just be a reproductive abnormality and could be a valid mechanism for an isolated female to jumpstart a new population.

Insights into Snake Evolution Stemming from the Discovery of the Earliest Ophidian

Much debate has centered on the ancestral ecology of snakes, with the leading hypotheses being that leglessness evolved as an adaptation to either a fossorial or aquatic lifestyle. Unfortunately, fossil material of early-diverging snakes remains scant. One snake, *Coniophis*, was described based on vertebral material collected from eastern Wyoming by O.C. Marsh in 1892. Subsequently, this fossil bed has been dated to the vicinity of the Cretaceous-Paleogene extinction event and cranial material attributable to *Coniophis* has been discovered but has remained undescribed. The authors of this paper officially described this material attributable to the snake *Coniophis* and evaluated it under an evolutionary framework. This cranial material exhibits a mix of ancestral ("lizard") and derived (ophidian) features. For instance, the teeth are long, cylindrical, and hooked like a snake, yet the maxilla maintains strong sutural connections with the other cranial elements much like non-ophidian lizards. The authors conducted phylogenetic analyses of living and fossil snakes using both cranial and vertebral material combined, as well as cranial and vertebral material separately. All three analyses found *Coniophis* to be the earliest diverging known snake. When specific characteristics associated with cranial kinesis were plotted onto the trees, only those associated with an intramandibular joint predated the split between *Coniophis* and other snakes, with most of the remainder immediately predating the split between Scolecophidia and Alethinophidia. The authors posit that with low neural spines, a kinetic mandible, and recurved teeth, *Coniophis* represents a fossorial predator on small vertebrates. Furthermore, as the majority of features associated with a kinetic skull immediately predate the most recent common ancestor of the diverse clade Serpentes and are absent in *Coniophis* and the similarly early-diverging *Najash*, these analyses lend credence to the idea that cranial kinesis may have served as a key innovation, permitting the incredible ophidian diversity we see today.

Photos Solicited for the New Show

HERPETOLOGISTS PAST AND PRESENT

Yes, you are correct. This is the current, about-to-be-former SSAR President in one of his more serious moments.

PHOTOGRAPH BY ALISON KELLY

To Be Revised for University of Kansas Meeting in 2015

In 1982, SSAR commissioned an audiovisual slide show to celebrate its 25th Anniversary Meeting in Raleigh (North Carolina). This 30-minute program was later enlarged and became a popular staple at SSAR meetings for nearly two decades. However, the technology used then (6 computer-controlled slide projectors) is now obsolete and must be completely revised using modern digital techniques.

SSAR has commissioned a new program, to debut at its 2015 meeting at the University of Kansas (July 30th through August 3rd). Color slides of herpetologists at work or play are hereby solicited. These may be color slides (which will be returned after scanning) or digital files (at 300 dpi/ppi or higher, preferably in TIFF but JPEGs are OK; best to burn files to CDs or DVDs). *All sources will remain confidential!*

Please send all of your images to David M. Dennis, 2708 Bigelow Drive, Sarasota, Florida 34239, USA or send them by e-mail to daviddennis@verizon.net. Be sure to include relevant data for each image (names of persons, dates, places, etc.).

Proposal to Alter Anole Taxonomy and Ecological Nomenclature

Phylogenetic work on squamates over the last decade has made great strides in clarifying relationships and diversification patterns. One recent study[1] used multilocus molecular phylogenetic approaches to examine evolutionary relationships within Iguania. Therein, the authors provided strong evidence for the paraphyletic condition of Polychrotidae sensu lato. To repair this violation of taxonomic rules, the authors proposed to resurrect the family Dactyloidae to encompass *Anolis* (anoles), which was found to be more closely related to Corytophanidae (basilisks) than to the nominative genus of Polychrotidae, *Polychrus* (bush anoles). Though there have been propositions to break up *Anolis* into several genera, these changes have not been widely accepted, resulting in a monogeneric Dactyloidae. A more recent study[2] used morphological and mtDNA sequence data for 189 taxa to generate a time-calibrated phylogeny of anoles. These analyses revealed eight mostly well-supported *Anolis* clades. The authors argue that leaving these species within a massive *Anolis* (387 species) obscures patterns of diversity and hinders research and scientific communication. To this end, they resurrect eight generic names for these clades and assign unsampled taxa to these clades presumably using previously published hypotheses. Furthermore, citing the fact that mainland anoles often are not morphologically convergent with their Caribbean "ecomorphological" counterparts, the authors propose to instead use the term "ecomode" to describe anole microhabitat specialist types. In addition to the five generally accepted types, they propose four additional ecomodes: ground, saxicolous, semiaquatic, and ground-bush. Using the recovered phylogenies, the authors performed analyses of ancestral reconstruction with regards to ecomode and geography of anoles. These analyses revealed the ancestral anole was probably a large, tree-dwelling South American lizard. Anoles diversified into the eight clades between 125 and 65 million years ago in the vicinity of Central America at a time when the region was an island archipelago that included the precursors to both modern day Central America and Greater Antilles. As these proposed changes affect taxonomy within a widely studied model system and are nonessential in that they are not an attempt to rectify paraphyly, they have generated considerable discussion, particularly on an internet forum frequented by anole researchers (Anole Annals: http://www.anoleannals.org/). Discussion has included the efficacy of using taxonomy to impart phylogenetic information, how recognizing several anole genera could increase appreciation of anole evolutionary and ecological diversity, the importance of taxonomic stability, and the feasibility of assigning unranked clade names in lieu of changing generic taxonomy.

Arbovirus Found in Two Pivipers

The Eastern Equine Encephalomyelitis Virus (EEEV) is a pathogenic virus found in the eastern United States. Known for affecting mammals, EEEV is spread by mosquito hosts with bird infections serving as a viral reservoir. Two mosquito species known to transmit EEEV feed on amphibians and reptiles. Ectothermic terrestrial vertebrates have been suggested as overwintering viral reservoir hosts for EEEV, supported by laboratory studies. In previous studies, experimentally infected snakes maintained infectious levels of virus longer than birds did, including during brumation. In this study, eight snake species in the Tuskegee National Forest of Alabama were tested for virus positivity. Cottonmouths (*Agkistrodon piscivorous*) were the most common snake sampled, accounting for over 40% of the site's potential EEEV host biomass, though Copperheads (*A. contortrix*) were also commonly encountered. The authors collected plasma from each snake, using a luminex assay to test for EEEV antibodies, indicative of exposure. To test for presence of the actual virus (rather than mere exposure), they extracted RNA samples from the plasma which were analyzed using qRT-PCR. Those that tested positive for EEEV RNA were subjected to virus isolation. Samples that tested positive and negative for the virus via the luminex assay were compared were compared with respect to viral RNA presence from the qRT-PCR. Significantly more EEEV-positive Cottonmouths were found via the luminex assay (54; 45%) than via the qRT-PCR assay (13; 10.8%). Nonetheless, one antibody-negative Cottonmouth did have EEEV RNA. Snakes most frequently tested positive for EEEV in the spring, with those numbers decreasing until August. One Copperhead also tested positive for the virus antibodies and RNA, but sampled Plain-bellied Watersnakes (*Nerodia erythrogaster*) and Racers (*Coluber constrictor*) indicated antibodies but no RNA. No differences in EEEV antibody presence were detected due to snake size, but larger snakes were slightly more often EEEV RNA positive. This study is the first to find EEEV (and not just antibodies) present in the serum of wild ectothermic vertebrates. Though lab studies showed that this was possible, this field study provides support for snakes as a vector for this virus and documents some of the patterns of this relationship.

Diversity of Color Sexual Dimorphism in Frogs

Differences in color among sexes (sexual dichromatism) is common in animals and has been investigated extensively in birds, fishes, and butterflies. In frogs, >90% of species exhibit size differences by sex, making this the most common sexually dimorphic trait. Sexual dichromatism has previously been documented in 25 frog species. The authors of this review paper identify 115 additional cases of color sexual dimorphism in anurans and analyze the ecological and evolutionary distributions of this phenomenon. Sexually dichromatic frogs may permanently change color or pattern at sexual maturity (ontogenetic dichromatism) or male frogs can undergo temporary color changes just for the breeding season (dynamic dichromatism). These color changes can vary from slight differences in shade to stark color and pattern changes. Ontogenetic sexual dichromatism was found to be more taxonomically widespread (18 families) than dynamic dichromatism (nine families), which is only found in crown frog lineages (Neobatrachia). Using a robust phylogeny to quantify phylogenetic signal, the authors found that both types of sexual dichromatism are independent of evolutionary history. Broad ecological factors, on the other hand, correlate with patterns of distribution in sexual dichromatism. Sexual selection is the most likely pressure driving dynamic color differences as these changes are only seen in the breeding season and in males. This temporary change may be limited by physiology—in most cases, males become more yellow or darker or lighter than their non-breeding coloration. Sexual niche partitioning is an alternative explanation for selection on ontogenetic dichromatism, supported by the presence of nocturnal, conspicuously colored sexually dichromatic frogs. This hypothesis of sexual niche partitioning may be well suited for study in frogs due to multiple independent origins of dichromatism. In brightly colored male ontogenetic changers (mostly Hylinae and Bufonidae), it is suggested that these changes are subject to similar selection pressures as those of dynamic color changers, but the effects are present year-round. In ontogenetic sexually dichromatic species where sexes both are brightly colored (common in African hyperoliid treefrogs), sexual selection in the form of female mate choice or within-sex competition are possibilities, but sexual differences in habitat use are also proposed. Future work on the genetics of color change pathways is needed to determine its adaptive value, as is further investigation into the ecological correlates of this phenomenon.

OBITUARIES

Herpetological Review, 2012, 43(4), 534.
© 2012 by Society for the Study of Amphibians and Reptiles

Paul M. Daniel (1924–2012): A Key Early Officer in the Society

Paul Mason Daniel, who was an early officer in The Ohio Herpetological Society (OHS), forerunner of the Society for the Study of Amphibians and Reptiles, died on 3 June 2012 in a retirement community in Adamstown (Maryland). He was 87. Paul was born in Philadelphia on 12 July 1924. After finishing high school in 1942, he enlisted in the U.S. Army's 34th Infantry Division and saw combat duty in North Africa and Italy; he won both a Purple Heart and a Silver Star. After discharge from the army, he matriculated at Miami University in Oxford (Ohio) to study zoology because of his boyhood interest in animals. After his marriage in 1948, he transferred to the University of Cincinnati (B.A. 1950). Paul and his wife then moved to Liberia in West Africa as missionaries. There he taught biology and math at Cuttington College (now University), founded by the Episcopalian Church of the United States; several of his students went on to become leaders in the Liberian government.

While in Liberia, Paul completed an extensive study of the life history of the Red-headed Agama (*Agama agama*), which was turned into his master's thesis (M.S., Miami University, 1954). He then became a faculty member at Miami—first in Physiology and then in Zoology—and later completed his doctorate (Ph.D., Ohio State University, 1964). At Miami, he taught various courses in field zoology, served as curator of the department's Hefner Zoology Museum, and helped to found Miami's Institute of Environmental Sciences. He mentored many students, several of whom had herpetological interests. One of them was Ray Ashton who went on to a career at the North Carolina State Museum (he chaired SSAR's silver anniversary meeting in Raleigh in 1982) and then to Florida where he championed conservation of the Gopher Tortoise. Paul also served as President of the Ohio Academy of Science. Beginning when he was still an undergraduate, he was very active in local Boy Scout programs (his 40 years of service later earned him a high award from Boy Scouts of America) and other community activities (he was named Oxford's Citizen of the Year). After retirement, he and his wife moved to the Philadelphia area.

In the Spring of 1958, Paul joined OHS and attended its first meeting in Toledo in June of that year. He quickly threw in his lot with the society's officers, who at that time were all teenagers. This was a risky decision for a college professor, but it was a huge morale boost for the society's officers. He gave the society some academic credibility at a time when it had none. In 1959, Paul became Vice-Chairman for Membership and thus was intimately involved in the society's rapid growth. He attended all of the early meetings and field trips (in those early years, the society also sponsored separate outings in the southern part of the state).

Paul's other contribution to the society's early history was to offer part of his master's thesis on agamid life history for publication. He had presented this research at the society's meeting in Cleveland, in 1960. His paper was issued in 1961 and created a small furor. Publication of a major paper on an African lizard in a state herp journal run by amateurs drew attention from leaders of the existing herp societies. I was Paul's editor. I received several quite critical letters that pointed out the inappropriateness of publishing this paper in such a place. I did seek the best advice, however, and had the manuscript reviewed by Arthur Loveridge, the leading expert on African herpetology who was then at Harvard, and by Robert Stebbins, the well-known specialist on lizard biology at Berkeley. They were listed on the publication as the reviewers. One letter-writer even asked me, incredulously, whether Loveridge or Stebbins had ever seen the manuscript at all! Well, as I replied, yes they did. I still have their reviews in my files today. Paul's paper was another milestone for OHS and helped to stake out the society's intention to be a scientific society, although at that time still a very small one. Paul published the other half of his master's thesis in *Copeia* (1960). He had a special interest in the herpetofauna of Adams County (Ohio), located in the southern part of the state along the Ohio River. He and his students had surveyed this county for many years because of its unusual physiographic features. They showed that it has the most diverse herpetofauna of any region in the state (31 species of amphibians and 23 of reptiles; published 1984).

In 1967, when the society changed its name to SSAR, Paul, like many others in Ohio, were quite unhappy because it meant that the society's focus was no longer going to be on Ohio, but its transition to a broader scope of interest had already been underway for several years. A decade later, when SSAR returned to meet in Ohio during America's Bicentennial Year, the conference was held at Miami University. Paul was on the Organizing Committee and it gave him much personal pleasure to welcome the society back home. By this time, Miami had two other herpetologists on its zoology staff, Douglas H. Taylor (who became SSAR's Publications Secretary and, later, its Treasurer) and Sheldon I. Guttman, who co-chaired that meeting, SSAR's 19th. Paul retained his membership in SSAR and watched the society's further growth with pride. His early involvement with the society, when its very existence was sometimes in question, remains his greatest contribution to the society's history.

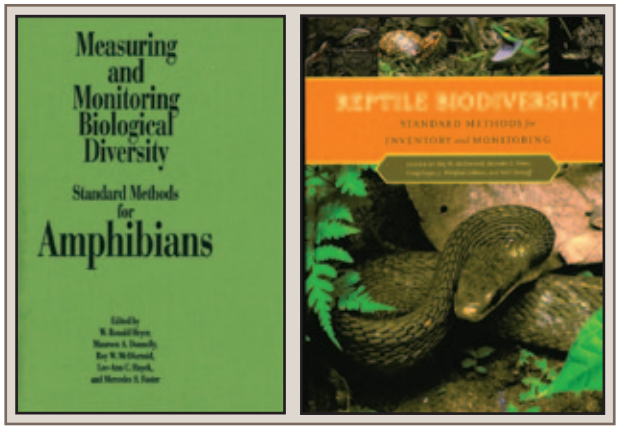
ZOO VIEW

> It is still so near pioneer times that people over forty remember wilderness to spare. But talk big to your boy nowadays about your own boyhood in the woods and you suddenly realize that you're stirring him up with urges less likely to profit him than knowing how to shrink heads or to build himself a sound harem.
>
> In Florida these days, you can still hear, under the mindless, glad din over industry coming in, the voices of the old ones—or of the young ones who have listened to the old ones—grieving over the passing of the wilderness. They are no longer watching landscapes wasting away. That happened long ago. What is going on now is just a lot of little cleanup operations, little scratchings-out of small tag-ends and patches of the past overlooked in the first waves of ruin.
>
> Archie Carr (1993) *Ulendo*

In a recent issue of *Connect*, the newsletter of the American Zoo and Aquarium Association (AZA), it was said that zoos and aquariums supported conservation initiatives to the tune of over US $130 million in 2011, an impressive sum indeed. These included both *in situ* and *ex situ* programs. Between 2007–2011, AZA's Conservation Endowment Fund awarded $419,694 to 22 reptile and amphibian conservation projects. This was out of 71 projects funded overall during that time period. The herp projects were conducted at the institution or in the field.



In 1983, since-retired curator Richard A. Sajdak from the Milwaukee County Zoo published an important article called "Herpetological research in zoos: A literature survey, 1977–1981" in the journal *Zoo Biology*. Of 1084 herp papers published in three major journals between 1977 and 1981, zoos were involved in 53. A total of 16 zoos contributed and nearly three fourths of these papers involved behavioral research.

Fifteen years later, Winston Card and David Roberts from Dallas Zoo and R. Andrew Odum from Toledo Zoo published a disturbing critique of zoo involvement in research (Card et al. 1998). They tried to survey 52 herp departments in the US to assess involvement with AZA-sponsored programs and formalized research programs during the past decade. Problem #1: less than half responded; Problem #2: nearly 80% of the 164 technical papers published were contributed by three institutions; Problem #3: over 40% of the non-technical articles were published by one institution; Problem #4: only four of the 20+ departments having what they described as "in-house research projects" had clearly defined objectives.

If one takes this analysis further, it is clear that some zoo herpetologists devote many hours to AZA-related activities, e.g., preparing studbooks and Taxon Management Accounts (TMAs), administering Taxon Advisory Groups (TAGs), and so on, and believing that these activities constitute research. That is really not true.

For some time, the U.S. Fish and Wildlife Service (USFWS) has prompted incorporation or support of field initiatives. In order to comply with some regulations protecting endangered species, we must demonstrate that our programs will enhance survivability in the wild by some direct involvement with wild populations. Sometimes, we are inexperienced or unprepared to conduct projects in the field, especially in developing countries. Extensive habitat destruction, hopeless bureaucracies, and nightmares obtaining permits and indifference by issuing officials were identified by Jonathan Campbell and Darrel Frost nearly twenty years ago: "If the effect of our statements is to make others press for legal restrictions in the taking of these animals, without serious protection of their habitats, then we can only lament that these people have failed what is, in effect, a conservation biology IQ test. They will have put a new roof on a burning house" (Campbell and Frost 1993). Can anyone argue that the situation has improved since that time of writing?

Because zoo keepers and biologists too often feel overwhelmed embarking on a project involving wild populations, I offer this solution to curators for initiating a study in the field: 1) arrange to work with a biologist who already has a field project in place; 2) use the keeper staff as field assistants and rotate them; 3) minimally, keepers must prepare for the field beforehand by reading the two books mentioned below; 4) zoo staffers benefit by learning a new skill set. Although zoo herpetologists may have spent time in the field collecting herps, they rarely have formalized training in conducting a field research project. I say this with certitude because during my career I have reviewed hundreds of résumés, from keeper to curatorial jobs, and this deficit is striking.

The task is easier now because these two books, one old and the other new, provide a comprehensive guide to conducting an *in situ* study on amphibians and reptiles. The first is *Measuring and Monitoring Biological Diversity. Standard Methods for Amphibians* (Heyer et al. 1994 and a Spanish-language edition issued in 2001). The new companion volume covers reptiles: *Reptile Biodiversity. Standard Methods for Inventory and Monitoring* (McDiarmid et al. 2012). There are four parts in the reptile volume: Introduction, Planning a Diversity Study, Sampling Reptile Diversity, and Conclusions. I hope that a Spanish version will be available in the future. In the foreword, Rick Shine sums up the challenge in studying biodiversity: "This is the book that I desperately needed at the beginning of my scientific career. Like most other young herpetologists, I had a pretty simple set of ideas about how to gather data—I'd just go out there, look for snakes, find some, catch them. and then write down anything that seemed useful (such as their sex or body size). And somehow or another, once I'd been doing that for long enough, I'd have a data set that could then tell all kinds of interesting stories about the biology of the creatures in question…And after talking with those more experienced herpetologists, it dawned on me that I actually needed to think about what I was going to do, and how I might ultimately use the data, *before* I started my fieldwork."

Before any field study is planned, both books should be thoroughly read to ensure that proper methodology is incorporated; no herpetologist's bookshelf should be without them.

NEW PAPERS OF IMPORTANCE TO ZOO BIOLOGISTS

Redefining the Role of Ex Situ Conservation

"We believe, however, that ex situ conservation has a more important role to play, especially in the face of the evidence of increasing extinction rates, exacerbated by climate change. We wish to stimulate discussions about the need to revise the contributions that ex situ approaches can make to conservation. Integrated conservation management approaches hold much potential but we must recognize the significance of institutional factors, not just the science that have hitherto constrained the development of direct conservation contributions from ex situ and integrated techniques. We question the continued validity of the in situ / ex situ distinction."

Pritchard, D. J., J. E. Fa, S. Oldfield, and S. R. Harrop. 2012. Bring the captive closer to the wild: redefining the role of ex situ conservation. Fauna & Flora International, Oryx 46(10):18–23.

Breeding Farms Used to Launder Smuggled Wildlife

"Wildlife breeding farms have been promoted to aid biodiversity conservation by alleviating the pressure of harvest on wild populations. There is, however, growing concern that many breeding farms are being used to launder illegally caught wildlife. Surveys of wildlife traders in the Indonesian provinces of Maluku, West Papua and Papua were conducted between August 2009 and April 2011 to assess the trade of the green python (*Morelia viridis*), the species currently exported in the largest numbers from Indonesia declared as captive-bred. In total, 4227 illegally collected wild green pythons were recorded during surveys and high levels of harvest were found to have depleted and skewed the demographics of some island populations."

Lyons, J. A., and D. J. D. Natusch. 2011. Wildlife laundering through breeding farms: Illegal harvest, population declines and a means of regulating the trade of green pythons (*Morelia viridis*) from Indonesia. Biological Conservation 144:3073–3081.

Role of Founder Effects and Natural Selection in Island Populations

Of interest to zoo biologists engaged in *ex situ* or *in situ* conservation efforts is the relative importance of founder events ("founder effects") and natural selection in maintaining genetic diversity, especially as population numbers decline to small levels. In an experimental study, Kolbe et al. introduced Brown Anoles (*Anolis sagrei*) to small islands in the Bahamas that had recently been cleared of lizards by a hurricane. They monitored both genetic and phenotypic responses among the descendents of these founder lizards on various islands, concluding that founder effects and natural selection jointly determine trait values in these populations.

Kolbe, J. J., M. Leal, T. W. Schoener, D. A. Spiller, and J. B. Losos. 2012. Founder effects persist despite adaptive differentiation: a field experiment with lizards. Science 335:1086–1089.

Amphibian Extinction Crisis is Here

In this review of current threats and recent research findings, Wake offers a broad perspective that addresses the truly dire future facing many amphibian species. Although chytridiomycosis receives considerable attention as the leading cause of population declines in Australia and Central America, other agents of extinction such as climate change and land-use changes may be more consequential over time. In a faintly hopeful note, he points out that amphibians have persisted through end-Cretaceous extinctions and Pleistocene climate changes, although present conditions of habitat loss make it less likely that populations will be able to respond geographically or elevationally in the face of warming temperatures.

HERPETOLOGICAL NOMENCLATURE

Extra! Extra! Extra! Read All About It! International Comm Approves Electronic Publishing of New Zoological Names!!!!

In one of the most momentous actions in the history of the International Commission on Zoological Nomenclature, the Commission has amended the International Code to provide recognition and regulation of names first published in electronic journals and books. Amendments to Articles 8 and 9 (what does and does not constitute publication); Article 21 (determination of date of publication); Article 78 (powers of the Commission), are designed to expand and refine methods of publication to include electronic ones. Full details of these changes, which are retroactively effective as of January 1, 2012, are available online (http://www.pensoft.net/journals/zookeys/article/3944/). Here I summarize the principal features of the changes:

Article 8.5. Works issued and distributed electronically must be published after 2011, state the date of publication, and be registered in the *Official Register of Zoological Nomenclature* (Zoobank) with evidence provided in the work itself that it has been registered prior to publication.

Article 9. What does not constitute publication adds three new prohibited categories to those enumerated in the 4th edition of the Code as follows: 1) after 1985 works produced by hectographing or mimeographing; 2) before 1986 and after 2012 works issued on optical discs; 3) preliminary versions of works accessible electronically in advance of publication.

Article 21. New wording clarifies the situation where a date is not specified in the original publication (21.7) and to prohibit the date of publication being derived from an online preliminary version of a publication. A new article (section 21.9) is added to establish the date of publication where a publication appears in both print and electronic form on different dates (whichever came first).

Article 78. This article as amended provides the authorization for the creation and eminence of the *Official Register of Zoological Nomenclature* (Zoobank).

The International Commission is to be congratulated for developing a carefully nuanced solution to the problem of electronic publication following their original commitment to it in principal in 2008. It should be noted that some of the concerns about Zoobank are met in the present set of amendments by requiring nomenclatural works, not individual names, to be registered.

New Cases of Herpetological Interest

Case 3561: *Anchisaurus* Marsh, 1885 (Dinosuaria, Sauropodomorpha): proposed conservation of usage by designation of a syntype for the type species *Megadactylus polyzelas* Hitchcock, 1865. BZN 69(1):44–50.

Case 2566: *Tropidolaemus* Wagler, 1830 and *Cophias wagleri* F. Boie, 1827 (currently *Tropidolaemus wagleri*) (Reptilia, Squamata, Viperidae): proposed conservation. BZN 69(2):116–121.

On the Type Species of the Snake Generic Name *Anilios* Gray, 1845 (Serpentes: Typhlopidae)

During most of the 20th century, worm snakes of the family Typhlopidae were referred to a single genus, *Typhlops* Oppel, 1811. Robb (1966b), on the basis of her discovery (1960, 1966a) of the presence of solid, coiled hemipenes and retrocloacal sacs in some male typhlopids, recognized those species with these features as the separate genus *Ramphotyphlops* Fitzinger, 1843. McDowell (1974) thought that the preoccupied name *Typhlina* Wagler, 1830 had priority over *Ramphotyphlops*, but Wagler's name was suppressed for purposes of priority by the International Commission on Zoological Nomenclature in Opinion 1207 (1982). Consequently, *Ramphotyphlops* was used until 2006 for Asian, Indo-Malayan, and Australian snakes having unique features of male anatomy.

Wallach (2006) proposed that *Ramphotyphlops* be divided on the basis of his unpublished, 1998, phylogenetic analysis into an Asian, Indo-Malayan, and Papuan genus (*Ramphotyphlops*) and a southern New Guinea-Australian genus which he named *Austrotyphlops*. Unfortunately, Wallach's name is a *nomen nudum* as the only characters that he mentions as diagnostic of the genus are those shared with all species of *Ramphotyphlops* for which those characters have been studied. Under Article 13.1 of the International Code of Zoological Nomenclature, in order to be available, a name published after 1930 must be "accompanied by a description or definition that states in words characters that are purported to differentiate the taxon." In addition, there are three available generic names that are senior subjective synonyms of *Austrotyphlops*.

The earliest name for the southern New Guinea-Australian clade is *Anilios* Gray, 1845, a masculine noun (an + helios = without sun), type species *Anilios australis* Gray, 1845 by subsequent

designation of Stejneger, 1904: 683. Wallach overlooked the fact that Stejneger had designated a type-species for this genus, although Williams and Wallach (1989: 9) accepted Stejneger's (1907: 260) reiterated designation. Wallach (2006) followed Loveridge (1957: 240) who made an invalid subsequent designation of *Anilios leachii* Gray, 1845 (= *Anguis jamaciensis* Shaw fide Hahn (1980: 60), or = *Anguis lumbricalis* Linnaeus, 1758 fide Roux-Estève (1974: 26), as the type species. Wallach further rejected the names *Libertadictus* Wells and Wellington, "1983", 1984 (type species by original designation and monotypy: *Onychocephalus bituberculatus* Peters, 1863) and *Sivadictus* Wells and Wellington, 1985 (type species by original designation: *Anilios nigrescens* Gray, 1845). Wallach attempted to dismiss these names as *nomina dubia* because their diagnoses are "inadequate and composite." However, the original descriptions of both nominal taxa are characterized by features that purport to differentiate them from other nominal genera. Consequently, these two names are available junior subjective synonyms of *Anilios* as their descriptions meet the requirements of Article 13 of the International Code.

The genus name *Anilios* is one of several names proposed for snakes currently included within *Ramphotyphlops* by most workers. Should the morphology-based generic arrangement of typhlopids proposed by Wells and Wellington (1985:40–41) gain recognition, *Anilios* probably will have priority over their name *Libertadictus* as it is likely that the included species (all Australian) have the distinctive hemipenial structure of that genus. Similarly, *Sivadictus* via their inclusion of *A. australis* as a species therein, as well as their generic diagnosis, places that name as a synonym of *Anilios*. The most recent (molecular) phylogenetic analysis of the Typhlopidae (Vidal et al. 2010) based on DNA sequence data confirms Wallach's finding that *Ramphotyphlops* is paraphyletic. However, their analysis did not include the type species of *Ramphotyphlops* (*Typhlops multilineatus* Schlegel, 1837) whose Indonesian distribution strongly suggests that it does not belong to the southern New Guinea-Australia clade as a putative *Anilios*. Consequently, the eventual usage of *Anilios* as a recognized genus, and the species it may contain awaits study within the perspective of the Vidal et al. (2010) analysis.

Tropical Fiord Habitat as a Year-round Resting, Breeding, and Feeding Ground for East Pacific Green Sea Turtles (*Chelonia mydas*) off Costa Rica

Golfo Dulce, located along the South Pacific coast of Costa Rica, is a fiord-like structure with an inner basin of more than 200 m depth, sheltered against the open ocean by a shallow sill of 60 m (Svendsen et al. 2006). These conditions make Golfo Dulce the only tropical fiord on the Pacific side of the Americas (Hebbeln et al. 1996) and one of only four tropical fiords in the world (Toft 2009). Current calculations list 4745 marine species in Costa Rica's Pacific waters, more than double the number reported from the Caribbean side of the country (Wehrtmann et al. 2009), and emerging data show Golfo Dulce to be a very diverse ecosystem, supporting at least 1028 species, from small invertebrates to large marine mammals (Morales-Ramírez 2011).

East Pacific Green Sea Turtles, *Chelonia mydas*, are known to utilize the waters around the Osa Peninsula, as are three other species: Olive Ridley, *Lepidochelys olivacea*; Hawksbill, *Eretmochelys imbricata*; and Leatherback, *Dermochelys coriacea* (Quesada-Alpízar et al. 2006). However, to date, limited data have been published regarding abundance and spatial and temporal distribution of *C. mydas* in the region. Sea turtle nesting activity near Golfo Dulce was first registered by Richard and Hughes (1972), who described the southwestern beaches of the Osa Peninsula as having one of the highest sea turtle track densities in the South Pacific region of Costa Rica. The Olive Ridley is the most common species on the nesting beaches just outside Golfo Dulce and while the Hawksbill is the least frequent species (Drake 1996), most of the Hawksbill nesting observations reported for Costa Rica during 2007–2009 took place in Corcovado National Park on the Osa Peninsula (Gaos et al. 2010). Here, we report the use of Golfo Dulce as a year-round resting, breeding, and feeding ground for East Pacific Green Sea Turtles.

Two onboard marine sighting surveys were conducted in Golfo Dulce from a 15-50 hp boat during the dry season months of January–February 2010 and the rainy season months of July–August 2011.The basic methodology has previously been described, including systematic interviews with 82 local fishermen and tour boat guides (Bessesen 2012), who were asked with what frequency they see sea turtles inside Golfo Dulce: always (N = 36), frequently (N = 33), occasionally (N = 10), rarely (N = 3), and never (N = 0). Combined onboard survey effort totaled 55 days (dry season, N = 30; rainy season, N = 25) and 424 observation hours. A blank on the field data sheet was used to indicate species ID reliability as definite (D), probable (P), maybe (M) or unconfirmed (U), but the two sea turtles marked M during the surveys were shifted to U for this reporting. Group size and behavior were also recorded.

A total of 177 sea turtle sightings were logged between 2010 and 2011. Forty-six of those sightings were marked U, while the remainder represented three species: *C. mydas* (N = 101), *L. olivacea* (N = 20), and *E. imbricata* (N = 10). GPS data showed each species using a different part of Golfo Dulce: Olive Ridleys were encountered in the lower half of Gulf, and Hawksbills were distributed coastally around the embayment, but 86.5% of East Pacific Green Sea Turtle sightings occurred in the upper half of the inlet. Based on areas of use by confirmed species and the locations of the U sightings, which were also concentrated in the upper half of the inlet, even more Green Sea Turtles may have been utilizing the northerly reaches of Golfo Dulce during the study period (Fig. 1). Use of the Gulf by *C. mydas* was comparable between the dry season (N = 53) and the rainy season (N = 48). In fact, *L. olivacea* was the only sea turtle species to show a distinct seasonal shift in numbers, increasing to coincide with its known nesting season on the Osa Peninsula during the rainy season (N = 19, vs. N = 3 in the dry season).

Chelonia mydas was the prevalent turtle species in Golfo Dulce, accounting for 57% of all turtle sightings. Digital images played an important role in species confirmation and photos or video were collected for 80% of our *C. mydas* sightings. Because a sighting could comprise one or more individuals of the same species in the same area at the same time, a single sighting might represent multiple individuals, as was the case for Green Sea Turtles when many were spotted simultaneously and could not be logged separately. Thus, the actual number of *C. mydas* counted during the study exceeded 288 individuals. Based on size, most appeared to be adults.

Green Sea Turtles were typically found floating motionless or quietly paddling at the surface in what appeared to be a resting

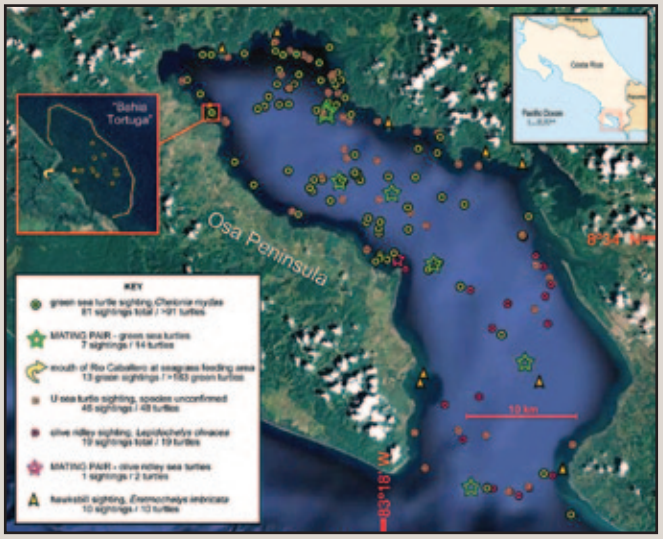

FIG. 1. Keyed GPS points for all of our 2010–2011 sea turtle sightings in Golfo Dulce. Insets: (upper right) location of Golfo Dulce in Costa Rica; (upper left) close-up view of sighting points in "*Bahia Tortuga.*"

FIG. 2. Surface behaviors of East Pacific Green Sea Turtles in Golfo Dulce. (A) Basking behavior – note the dry shell. (B) Copulating pair.

state, with liberal exposure of the carapace indicating some degree of thermoregulation (Fig. 2A). Head position was variable, from upright to hanging at or slightly below the water surface and turtles in this basking position (N = 70) often remained at the surface for several minutes. Mating pairs of *C. mydas* (N = 7) were also documented during our surveys (Fig. 2B). Although Green Sea Turtles showed positive selection for the upper half of the inlet, breeding was recorded in all four quadrants of Golfo Dulce and the behavior did not appear to be seasonally driven (dry season, N = 4; rainy season, N = 3). It should be noted that while there are a few locally known nesting sites for Green Sea Turtles along the banks of Golfo Dulce, including Playa Preciosa, nesting did not seem to be a major activity inside the inlet.

In many neritic habitats, the diet of adult *C. mydas* is predominantly herbivorous (Bjorndal 1980; Devaux and DeWetter 2000; Seminoff et al. 2002) and a coastal tracking study by Senko et al. (2010) showed Green Sea Turtles off the Pacific coast of Baja California Sur, Mexico, spent 69% of their time over areas of seagrass and 59% in depths < 5 m. In Golfo Dulce, a considerable number of Green Sea Turtle sightings occurred in a > 400 m^2 area where shallow subsurface topography supported an abundance of seagrass. The bed was situated around 40.058°N, 26.598°W, near the mouth of Rio Caballero. Underwater photographs revealed two species of seagrass. Only two species have been reported on the Pacific side of Costa Rica, *Ruppia maritima* and *Halophila baillonis* (Cortés 2001; Cortés and Salas 2009). While one of our specimens was clearly *H. baillonis,* the other, filamentous species was challenging to confirm via photos. It may have been *R. maritima* but was more likely *Halodule beaudettei* (J. Cortés, pers. comm.; J. Samper-Villarreal, pers. comm.), a grass found in Panamá, which Cortés (2001) believes might also grow in Costa Rica.

We came to call the seagrass bed "*Bahia Tortuga*" ("Turtle Bay") because it supported extensive cheloniid activity and appears to be a critical feeding habitat. At least 183 individual *C. mydas* were observed in the area with total estimated numbers exceeding 500 turtles. All photographs taken in Bahia Tortuga confirmed the sightings to be *C. mydas* with the exception of one obvious Hawksbill seen near the mangrove roots (described as emerging habitat for that species; Gaos et al. 2012). In Bahia Tortuga, Green Sea Turtles spent their time submerged and were never observed floating at the surface as described in other parts of the Gulf. Green Sea Turtles were sometimes visualized from the boat as they swam subsurface in the shallowest water (<3 m) and skin diving allowed one observer (BLB) to view several turtles near the seagrass floor, although actual feeding behavior was not observed. The majority of sightings in Bahia Tortuga occurred from the research vessel, floating quietly with the motor off. During these periods of silent observation, turtle heads popped up as various individuals surfaced to breathe. Carapaces were not visible and cranial exposure was fleeting, never lasting more than 1–2 sec, a behavior possibly common in foraging habitats (Hazel et al. 2009). Loud exhales indicated extended breath-holding. Since passing boats were unlikely to see any turtles, the area was generally unrecognized as a turtle hotspot and was at the time undisturbed by human activity.

Globally, Green Sea Turtle populations have fallen into collapse from anthropogenic impacts (Devaux and DeWetter 2000; Mancini and Koch 2009; Marquez et al. 1982; Seminoff et al. 2002). Numbers are said to be dropping precipitously in Golfo Dulce as well. Several interviewed fishermen with up to four decades experience in the Gulf stated that recent years have brought a decline in sea turtles of at least 30%. Understanding habitat use is fundamental to the conservation of these large marine vertebrates. In the East Pacific, the Green Sea Turtle is a highly migratory species and corridors between the Galápagos Islands and the Baja California peninsula have been identified; these serve as routes of travel between feeding grounds and nesting sites (Amorocho and Reina 2007; Amorocho et al. 2012). Tag recovery data have shown nesting females traveling from México to Colombia and from the Galápagos Islands to Costa Rica (Alvarado-Diaz and Figueroa 1990), including Golfo Dulce (Chacón et al. 2011). Our data now indicate that East Pacific Green Sea Turtles are using Golfo Dulce as a resting, breeding, and foraging area throughout the year, suggesting this tropical fiord may be an important site within the Green Sea Turtle migratory corridor in the East Pacific.

Acknowledgments.—We would foremost like to thank Jorge Largaespada for his dedication to this work. We gratefully thank Osa Conservation for providing key provisions for the study, Osa Adventuras, El Tigre Fund, Walter Aguirre Aguirre, Juan Diego Morales Cambronero, Marvin Villalabos Palma, and Dan Hughes for field support, and Jorge Cortés, Pilar Bernal, and Didher Chacón for valued insight. This project was funded by a Greg Gund Memorial Fellowship.

Here be a Dragon: Exceptional Size in a Saltwater Crocodile (*Crocodylus porosus*) from the Philippines

Crocodiles (Reptilia: Crocodylia) are generally regarded as the largest living reptiles by mass (Britton 2003). Exceptionally large individuals regularly attract mainstream attention, often enhanced by unrealistic and exaggerated accounts of their size and behavior. Actual evidence on the upper size limit of crocodiles is lacking and romantic accounts and misleading photographs are often the only remains. Skulls found in museums and private collections provide a tantalizing glimpse into the size of their former owners, yet total lengths are usually not available, the techniques used to obtain them are not known, and the veracity of such measurements is questionable (Greer 1974; Whitaker

and Whitaker 2008). Limited verification is possible using existing formulae for predicting total length (TL) from skull measurements such as dorsal cranial length (DCL; e.g., Verdade 1999; Webb and Messel 1978; Wu et al. 2006). However, such formulae are typically derived from a subset of possible size ranges, and become increasingly inaccurate if applied outside those ranges to the largest examples of a species. Not only do crocodilian body parts show allometric change with increasing size (Gans 1980), the rate and direction of change is not constant (Hall 1985; Hall and Portier 1994) and there is increasing variability particularly near the maximum upper size limit (Whitaker and Whitaker 2008). As there is a dearth of data available from thorough and systematic measurements of very large crocodiles, our ability to predict TL from other variables including DCL is compromised near the upper limit. Such information is useful across a number of disciplines including paleontology, conservation and population management (Brochu 2001; Schmidt-Nielsen 1984).

We present accurate measurements for an exceptionally large Saltwater Crocodile (*Crocodylus porosus* Schneider 1801) that was captured alive from Mindanao in the Philippines. We compare these measurements with those of other exceptionally large crocodiles and discuss factors responsible for exceptional size.

Background.—The capture of an exceptionally large male *C. porosus* from a small creek not far from Bunawan in the Agusan del Sur province of Mindanao in the Philippines made international headlines on 3 September 2011. This crocodile was captured after a two-year effort to remove the animal thought responsible for the death of 12-year-old Rowena Romano in Lake Mihaba in Agusan Marsh on 7 March 2009 (Sistante 2009) and later in mid-2011 the unreported disappearance of a fisherman close to Bunawan village (R. Sumiller, pers. comm.). An experienced member of the Palawan Wildlife Rescue and Conservation Center (PWRCC), Ernesto "Lolong" Cañete, died of a heart attack in late August 2011 shortly before the crocodile's eventual capture. The crocodile was named "Lolong" in his memory (R. Sumiller, pers. comm.).

Lolong's capture was coordinated by wildlife specialist Ronnie Sumiller and other PWRCC members. Steel nooses baited with Carabao (*Bubalus bubalis carabanesis*) meat were deployed hanging from trees along the creek. The first four nooses were destroyed by the crocodile's struggling before a fifth, thicker-cabled noose was successful. The remains of the other nooses were found fastened around the crocodile's upper jaw. Dozens of people were reportedly required to haul the crocodile onto the bank where his jaws and legs were bound using ropes (E. Elorde, pers. comm.). Key PWRCC staff who were not present on the capture night provided additional guidance by mobile phone. Over 100 people were required to haul the crocodile by cart along the river bank to the nearby village and a floating pontoon had to be constructed to float the crocodile across the creek to access the only available road. The crocodile was then transferred to nearby holding facilities and now resides at Bunawan Eco-Park and Research Center.

There was considerable international interest in the total length of Lolong. The crocodile which killed Rowena Romano was estimated by a witness to be "30 ft" (9.1 m) in length, whereas the crocodile seen hunting carabao near the village shortly before capture was suspected to be closer to "16 ft" (4.9 m) long (E. Elorde, pers. comm.). His true size only became apparent during capture. Media reports of his length were inconsistent, ranging from 6.1 to 6.4 m (20–21 ft). It was not known at the time how accurately the crocodile had been measured, what method had been used, or whether the figure had been reported correctly. However, photographic and video evidence showed his size to be exceptional. This was sufficient to attract serious interest in verifying the measurement and Natural History New Zealand dispatched one of the authors (AB) to visit Bunawan and independently measure the crocodile where it would be witnessed and documented. Funding was provided by National Geographic.

Table 1. Measurements of Lolong. See Materials and Methods for the difference between Method A and Method B. Method A is considered the principal measurement. All measurements are illustrated in Fig. 2. All length measurements are taken from tip of premaxilla (snout). All width measurements are taken at the widest point.

Measurement (mm)	Method A	Method B
Dorsal cranial length (DCL)	700	694
Snout–eye length (SEL)	496	495
Maximum head width (MHW)	450	450
Maximum cranial width (MCW)	228	228
Inter-orbital width (IOW)	84	84
Cranial height (CH)	363	363
Snout–pelvis length (SPL)	2851	2844
Snout–scute junction (SSJ)	4982	4949
Total length (TL)	6170	6095

Materials and Methods

Capture and restraint.—One of the authors (AB) measured Lolong in his enclosure at the Bunawan Eco-Park on 9 November 2011 at 1400 h local time. Measurement conditions were considered ideal. Lolong was lying relatively straight on the level concrete floor of a recently-drained pool. A combination of chemical and physical restraint was employed to facilitate accurate measurement, to improve safety for personnel, and to ensure the crocodile's welfare. Chemical restraint was achieved using pancuronium bromide, the dose (2 x 2 mg, 40 minutes apart) intended to provide temporary partial immobilization (after Bates et al. 2004), plus diazepam (10 mg, single dose) to provide temporary mild sedation. Both drugs were injected IM into opposite sides of the tail. As Lolong was outside the size range of crocodiles for which either drug had previously been tested, we used highly conservative dose rates—the minimum required dosage to permit safe handling without compromising handler welfare. Ventilation rate and eye blink response were monitored throughout the procedure.

Induction took two hours, at which point the crocodile was capable only of lethargic movements of the head, limbs, and tail tip. At this point standard physical restraint was employed: the head was secured with a controlling rope noose on the upper jaw, a second noose around both jaws to close them remotely through tightening, and thick damp towels over the eyes to reduce visual reactions. At this point a five-person team engaged the crocodile from behind, applying downward pressure to the top of the head, the pectoral and pelvic regions, and the body and tail, while lifting each limb from the ground to limit traction (Fig. 1). The jaws were secured shut using duct tape, with the nostrils free to permit normal breathing. At this point, handling and close-quarters measurements were considered safe. Measurement activities lasted approximately one hour, after

FIG. 1. Lateral view of Lolong under restraint during measurement procedure.

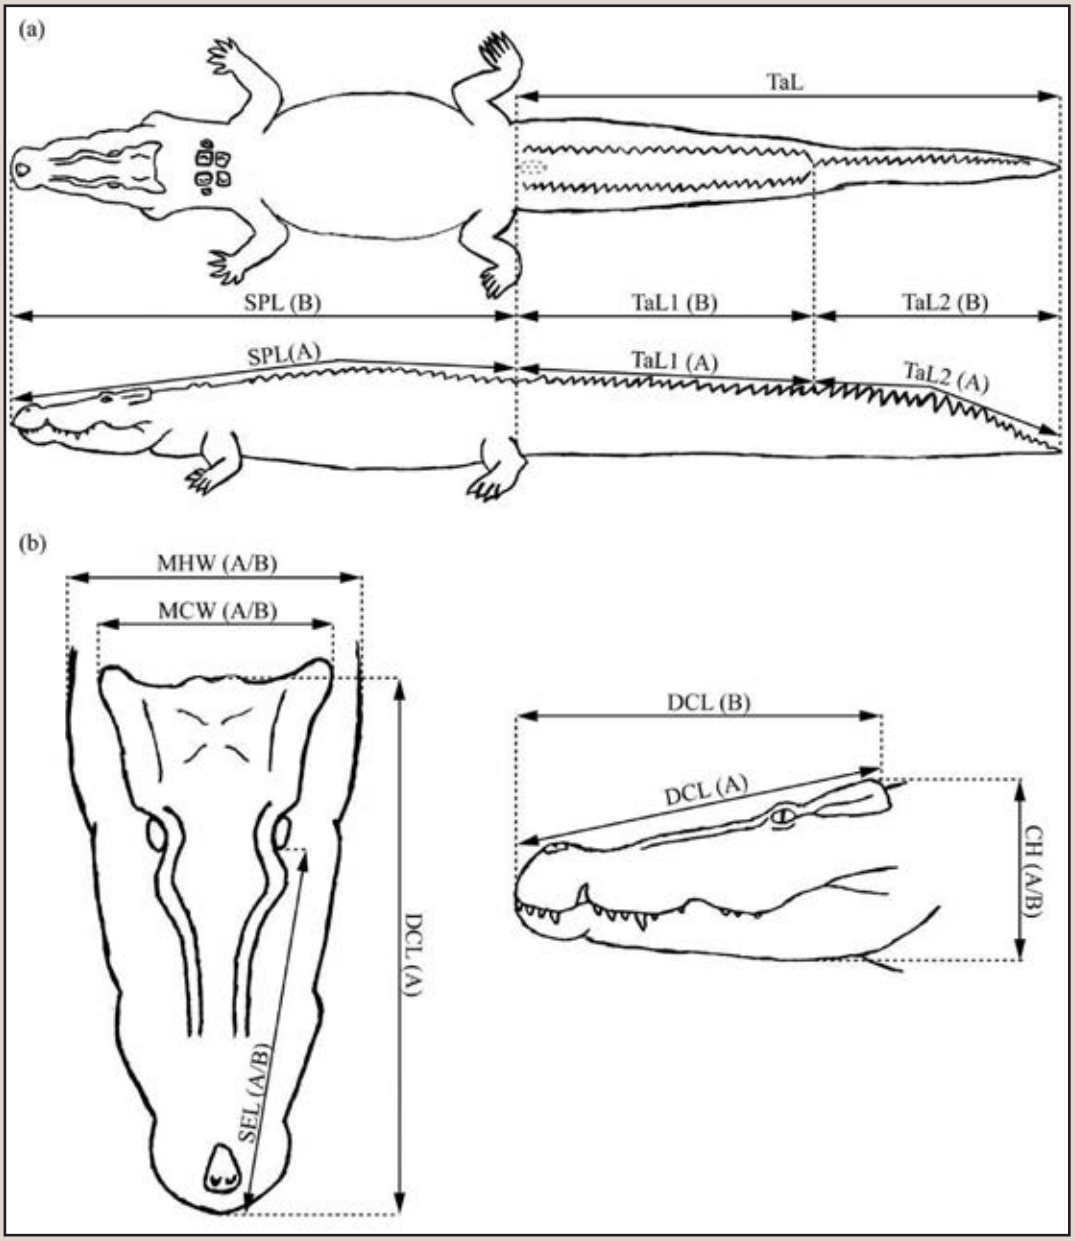

FIG. 2. Top-down and profile diagrams of entire crocodile (a) and head (b) illustrating measurements taken using Method A (A) and Method B (B). DCL = dorsal cranial length; SEL = snout–eye length; MHW = maximum head width; MCW = maximum cranial width; IOW = inter-orbital width; CH = cranial height; SPL = snout–pelvis length; TaL = tail length; TaL1 = anterior tail length; TaL2 = posterior tail length; SPL+TaL1 = snout–scute junction (SSJ); SPL+TaL1+TaL2 = total length (TL).

which all physical restraint was carefully removed using established safety protocols. A reversal agent for pancuronium bromide (e.g., neostigmine methylsulphate) was not used and the drugs were allowed to metabolize naturally while the crocodile was under observation. Lolong was exhibiting normal behavior six hours post-injection, moving around his enclosure with ease.

Measurement.—Lolong's head and tail were straightened carefully before any measurement took place. He maintained this posture throughout the procedure. Measurements concentrated on head dimensions and body length variables that were unlikely to be influenced by body condition in any way (Figs. 2a, 2b), unlike for example belly width. All measurements were taken using a flexible but non-stretchable steel tape with a millimeter scale. Conversion into other units (e.g., feet) was done after the fact. The tape was held taut for each measurement and where necessary straight wooden rods held perpendicular to the ground were used as boundary markers for specific measures (e.g., maximum head width; Fig. 1).

There is no clear agreement on a "standard" method for measuring crocodilian dimensions. We generally followed methods previously published for *C. porosus* (Webb and Messel 1978) slightly modified based on our experience on practical techniques with wild crocodiles. We used DCL specifically for "head length" to avoid any confusion with skull measurements that have occasionally confused mandible length with head length (Whitaker and Whitaker 2008). Skull widths and heights were taken at the maximum points. Snout–pelvis length (SPL, Fig. 2a), to the posterior margin of the hind legs joining the pelvis, was used as a substitute for snout–vent length (SVL) because it was highly impractical to roll such a large crocodile onto its back and there were concerns about the welfare implications of doing so with such a heavy crocodile on concrete. Previous comparisons (A. Britton, pers. obs.) suggest that SPL and SVL differ by less than 1%.

To address possible disagreement over the most suitable method for body length measurements, two methods were used for comparative purposes (Table 1, Fig. 2a). Method A used a steel tape along the dorsal midline from snout tip to tail tip following the slope of the skull and latter part of the tail. Method B used the horizontal distance from snout tip to tail tip exactly parallel to the ground. In practice Method B gave fractionally shorter lengths than Method A (by around 1% in large individuals) and yet Method A is more frequently used (A. Britton and R. Whitaker, pers. obs.), simply because it is more practical especially with large individuals that are difficult to move. Measurements using Method A are therefore more relevant because they allow more meaningful comparison with measurements of other large crocodiles. It should be noted that Lolong's tail tip did not appear to be damaged.

Lolong's mass was recorded at a nearby truck weigh-bridge during transport to his captive holding facilities on 3 September 2011. As it was logistically impractical to verify his mass during our visit, his reported mass on that date is provided here. There is no reason to believe that rigor in this simple measurement was lacking and we considered it valid.

Results

Using Method A, Lolong's total length (TL) was 6.17 m (20.24 ft; Table 1), with a dorsal cranial length (DCL) of 700 mm (27.6 in). Ratio of DCL to TL was 1:8.8. Snout–pelvis length (SPL) was 2.85 m (9.35 ft). Therefore tail length (TaL) was 3.32 m (10.89 ft), with TaL to TL ratio of 1:1.9. Snout–scute junction (SSJ) was 4.98 m (16.34 ft), therefore we calculated anterior tail length (TaL1) as 2.13 m (6.99 ft) and posterior tail length (TaL2) as 1.19 m (3.90 ft). The ratio TaL2 to TaL is 1:2.8. Measurements using Method B are provided for comparison (Table 1). All measurements differed by less than 1% between Methods A and B except TL, which differed by 1.2%. Lolong's net mass (accounting for the trailer weight) was 1075 kg (2370 lbs).

General body condition was good, with normal muscle tone and fat deposits typical of a large wild crocodile. Age cannot be determined by physical examination, but there were no obvious signs of senescence. Age was estimated subjectively at approximately 50 to 60 years based on indicators such as level of skull rugosity, health of teeth alveoli, height of dorsal scute keels, and overall appearance, which can be compared with prior observations. Very little historical scarring was found on the skin, and no limbs, toes, or parts of the tail were missing, which was considered unusual for such a large wild crocodile. The ventral surface was not examined. Recent superficial injuries evident in a handful of locations (pads of feet, flanks, dorsal osteoderms, snout) appeared to have been caused by rope abrasion incurred while struggling during capture and transport. All recent injuries appeared to be healing normally; almost all scab tissue had fallen off, revealing fresh, non-pigmented or partially-pigmented skin tissue.

Discussion

Lolong's TL, at 6.17 m (20.24 ft), makes him the largest wild crocodile ever captured alive. The TL measurement taken by Edwin Elorde shortly after capture (6.4 m, 21 ft) was slightly higher than the one obtained here. Although measurement inaccuracy may be a factor, it is also likely a result of the crocodile's posture when it was strapped to a cart with the tail hanging onto the ground. The weight of the tail muscle would be sufficient to pull vertebrae apart, enough to account for most of the additional 20 cm (7.9 in) length, underlining the need for measurements to be taken with a crocodile lying on flat, level ground.

There are a number of reports of wild-caught crocodiles with greater TL, but these are either difficult to verify or are from incomplete specimens (e.g., dried skins; Whitaker and Whitaker 2008). While it is improbable that Lolong is the largest *C. porosus* ever found, it is disappointing that the evidence for larger specimens is so incomplete. This evidence comes almost entirely from skulls residing in museums and personal collections around the world. Data from their original owners are often lacking, with TL either not recorded or impossible to verify, and even the country of origin is doubtful in some cases. However, it is possible to use known relationships between each DCL and TL to estimate the total length of the crocodile from which each skull was derived. Unfortunately, the only thorough analysis to date for *C. porosus* uses data from relatively small hatchlings up to sub-adults and the formulae were obviously never intended to be extrapolated for much larger animals (Webb and Messel 1978). It is apparent from the limited data available that skull shape is subject to greater variation with increasing TL, DCL becoming a smaller proportion of TL with increasing size. The DCL:TL ratio for smaller crocodiles has long been thought to be around 1:7 (Bellairs 1970; Greer 1974; Wermuth 1964) but this would under-estimate Lolong's length by over a meter (3.3 ft). The DCL:TL ratio for large *C. porosus* is closer to 1:9 (Whitaker and Whitaker 2008). Therefore, caution must be used when estimating TL based on DCL of existing museum skull specimens.

The largest known *C. porosus* skull is housed at the Paris Museum (MNHN PMP specimen #A11803 = old museum collection #7738) originally from Cambodia. It has a DCL of 760 mm (29.9 in), making it 8.6% longer than Lolong's skull. If we apply a DCL:TL ratio of 1:9 for this skull, TL is estimated at 6.84 m (22.4 ft) which is 11.3% longer than Lolong's TL. Although the actual TL was never preserved, these figures strongly suggest a nearly 7 m (almost 23 ft) crocodile. We can compare this with another slightly smaller skull (currently in the private collection of Shivendra Narayan Bhanja Deo, the Yuvaraj of Kanika in Bhubaneshwar, Orissa) of DCL 730 mm (28.7 in), originally from the Indian Bhitarkanika province, reported to have come from a 7 m (23 ft) *C. porosus*. If those figures are true then DCL:TL ratio would be 1:9.5, sufficiently high for minor skepticism but still feasible. Applying the 1:9 ratio to the Bhitarkanika skull gives an estimated TL of 6.6 m (21.7 ft). The truth is unlikely to be far from these figures and there is a strong sense that 7 m (23 ft) is likely the maximum possible length for *C. porosus*.

After Lolong, the best documented evidence of a record-sized crocodile comes from Obo village on the Fly River in Papua New Guinea (Montague 1983). This crocodile drowned in a fishing net set for barramundi fish and after 50 men hauled the crocodile onto the bank they found an entire Rusa Deer (*Cervus timorensis*) carcass in the stomach. The crocodile's skin had already been removed and salted when Jerome Montague and one of the authors (RW) visited the village, but the skin plus decapitated head measured 6.2 m (20.3 ft). The authors considered this likely an underestimate considering possible shrinkage of the skin plus an incomplete tail tip, suggesting a TL closer to 6.3 m. The DCL of this crocodile was 720 mm (28.3 in), which at 6.2 m TL would indicate a DCL:TL ratio of 1:8.6, or 1:8.8 considering the likely 6.3 m TL. While not a complete or living specimen, this is still considered the largest *C. porosus* ever measured and documented.

There are several unverified reports of even larger wild crocodiles, the most popular being a 7 m plus (over 23 ft) *C. porosus* sighted within the Bhirtarkanika Wildlife Sanctuary in Orissa, India, in 2006 (Whitaker and Whitaker 2008). However, this was not a measurement but a size estimate taken from a boat and regardless of the skill of the observers it cannot be compared to a verified tape measurement, especially considering the uncertainty inherent in visual size estimation in the wild (Bayliss 1987). Another famous giant crocodile shot on the Norman River in Australia in 1957 was reported by the shooters to be over 8 m (approx. 26 ft). While it seems likely that an exceptionally large crocodile was shot, no actual evidence was ever taken. For a crocodile whose length exceeds that of any other record by a large margin, a high degree of skepticism is understandable when bearing in mind the track record of inaccurate or exaggerated size records (Greer 1974; Whitaker and Whitaker 2008).

In 2011 Guinness World Records announced that a 5.48 m (18 ft) *C. porosus* called "Cassius" at Marineland Melanesia on Green Island, Queensland, was the largest crocodile in captivity (Guinness World Records 2011). Cassius was captured alive from the Finniss River in the Northern Territory, Australia, in 1984, and was reportedly missing a small amount of his tail tip. Lolong is 69 cm (2.2 ft) longer than Cassius. The only other captive crocodile that rivals Lolong for length is "Yai" at Samutprakarn Crocodile Farm, Thailand, who was measured in 2000 at 6.0 m (19.7 ft) with a mass of 1114 kg (2455 lbs). While Yai will have grown slightly in the last decade, it seems unlikely that he currently exceeds Lolong. Yai is also the result of artificial captive hybridization between *C. porosus* and *C. siamensis* (Siamese Crocodile), his size potentially the result of heterosis (or "hybrid vigor"; Shull 1948). In June 2012 Guinness World Records pronounced Lolong to be the largest crocodile in captivity (Guinness World Records 2012).

To address the question of why extremely large crocodiles are so rare, it is instructive to look at factors responsible for growth and size. An early analysis suggested that males cease growth from 3.9 to 6.0 m (12.8 to 19.7 ft; Webb et al. 1978), yet it is widely known that environmental and social factors that influence access to required resources (e.g., desired temperatures, access to water, access to basking sites, food availability and quality, and social stress) can have a significant impact on health and growth rates (Coulson and Hernandez 1983; Dalrymple 1996; Lang 1987; Webb 1985). Crocodilians in captive situations are highly sensitive to stress and the availability of resources, which have a marked effect on growth rate (e.g., Choudhury and Bustard 1983; Lance 1994; Smith and Marais 1994). We also know that genetic factors play a significant role in post-hatching growth and behavior, as does the incubation environment (Allsteadt and Lang 1995; Isberg et al. 2004).

Growth rate in crocodiles is based on a von Bertalanffy growth curve, being fastest in juveniles and progressively slower in adults. The greatest proportion of growth occurs in the first 15–25 years, to around three-quarters of maximum size, although faster-growing individuals appear to sustain rapid growth for longer (Webb et al. 1978). Slow-growing juveniles become smaller adults, growth rates falling too low to ever achieve very large sizes. In such individuals growth essentially stops in older animals (Webb et al. 1978; Woodward et al. 1995). Conversely it is the fast-growing juveniles that reach the largest adult sizes and grow for longer. It is incorrect to assume that extremely large crocodiles are necessarily the oldest crocodiles. For example, the hybrid Yai reached 6 m (19.8 ft) in less than 30 years and a purebred *C. porosus* ("Jaws") at Madras Crocodile Bank reached 5.13 m (16.8 ft) in 38 years. Most wild *C. porosus* take at least 15 years to reach 3.5 m (Webb and Manolis 1989).

In order to achieve maximum growth rates and size in the wild, crocodiles require greater access to optimal environmental conditions particularly when young, access to all necessary resources when desired, and minimal growth-inhibiting stress. Given the role that stress plays in inhibiting growth, it is likely that exceptional size can only be achieved when crocodiles do not encounter humans on a regular basis. Lolong, for example, appears to have spent his entire life in and around Agusan Marsh, an area that sees very low human traffic due to difficulty of access and where overall crocodile densities appear to be well below carrying capacity (Pontillas 2000). The lack of scarring and body injuries also suggests limited competition. Under such favorable conditions for a crocodile, individuals that may also have been genetically predisposed for faster growth would have excellent opportunities to thrive and reach exceptional sizes. How important genetic factors are in influencing growth rates and maximum size in wild *C. porosus* remains unclear, although it is possible that extensive and widespread hunting of populations until the 1970s may have eliminated genetic traits that had selected for exceptionally large crocodiles preferred by trophy hunters, traits that may exist today only extremely rarely.

Acknowledgments.—AB thanks the following for the opportunity to visit Bunawan and measure Lolong: Office of the Mayor of Bunawan (Mayor E. Elorde, R. Nuer), Palawan Wildlife Rescue and Conservation Center (including R. Sumiller), Protected Areas and Wildlife Bureau (including T. M. Lim, Dr. E. Toledo, J. de Leon),

Natural History New Zealand (NHNZ), C. Meade, N. Javellana, K. Siney, R. Taylor, B. Maddul, R. Ordona, and the communities of Barangay Nueva Era, Barangay San Marcos, and Barangay Consuelo. Funding was provided by National Geographic Channel and NHNZ. RW and NW thank the Trustees and Staff at Madras Crocodile Bank Trust for support and assistance. We also thank Brandon Sideleau for providing the artwork. All capture protocols and measurement procedures were carried out according to Australian Federal guidelines (DEWHA 2009) and with the permission of the Philippine Protected Areas and Wildlife Bureau.

Farm-raised "*Salmonella*-free" Turtle Hatchlings Do Not Excrete *Salmonella* in Home Aquariums

A rise in reptile-associated cases of salmonellosis in children under ten years of age led the United States Food and Drug Administration in 1975 to create regulations that prohibited the inter- and intrastate sale of turtles with a carapace length less than four inches (ca. 10 cm) while educational sales and overseas sales continued unchanged (Cohen et al. 1980). The rationale for this ban was that turtles carry *Salmonella* as part of their normal assortment of bacteria. *Salmonella* may be shed intermittently (Kaufmann et al. 1967) and complete eradication of *Salmonella* in turtles through treatment would be complicated. By prohibiting the sale of small turtles, the legislature limited the possible exposure to *Salmonella* assuming that larger turtles would make less desirable pets for young children.

To insure that pet turtle farmers upgrade their facilities to assist the industry in its effort to lift the FDA ban, the Louisiana Department of Agriculture & Forestry requires turtle farmers to be licensed and regulates the industry through Act 770 Regulation of Pet Turtles, Regular Session 1990. In particular, turtle hatchlings produced on Louisiana farms are required to be laboratory tested and shown to be free of any trace of *Salmonella* bacteria before they can be sold. Currently, most Louisiana turtle farmers now produce "*Salmonella*-free" turtles by washing the turtle eggs with chemical disinfectants rather than treatment with antibiotics like gentamicin (Mitchell et al. 2007).

The purpose of the present study was to investigate whether it is possible to maintain the *Salmonella*-free status of turtle hatchlings in aquariums similar to those found in homes. To test our hypothesis, *Salmonella*-free turtle hatchlings were maintained in such aquariums and monitored for a year for any evidence of *Salmonella* bacteria.

Methods

Turtles and their facilities.—The aquatic Red-eared Slider (*Trachemys scripta elegans*) is the mainstay of the Louisiana turtle producers and the primary turtle hatchling species sold (Iazdjoo et al. 1987). In late August 2008, we obtained 80 one-week-old *T. scripta elegans* hatchlings from a Louisiana turtle farm. Fifty hatchlings came from a group of eggs that were sanitized with 500 ppm sodium hypochlorite and 30 came from rinsed but unsanitized eggs. Each turtle was individually kept in 50 ml of sterile water for 30 days. After 30 days, the water containing feces was assayed for *Salmonella* as described below (Michael-Marler et al. 1983). The hatchlings that came from sanitized eggs tested negative for *Salmonella*, while the hatchlings that came from unsanitized eggs tested positive for *Salmonella*. The turtles were then transferred into three aquarium tanks each with approximately 30 L of water for an additional 30 days and the aquarium water was again assayed for *Salmonella*. The *Salmonella*-free turtles were split into two tanks with 25 turtles in each tank, while the *Salmonella*-containing turtles were housed in their own tank. This additional incubation was to ensure that the hatchlings were healthy enough to be used in a year-long study and that they would eat commercial pet turtle food (Tetra turtle food). If *Salmonella* were resident within these turtle hatchlings, the fecal mater from eaten food would likely have *Salmonella*.

Forty *Salmonella*-free turtle hatchlings were divided into four groups of ten turtles. Each group of ten was housed in a commercially-sold 20-gallon (75.7 L) glass tank that included a floating island, a Tetra Whisper EX20 water circulation pump (110 gph) with a carbon containing bio-bag and bio-scrubber (bristle design), and a fluorescent light fixture. The lights were attached to a timer to provide 12 hours lights and 12 hours dark. Tanks contained 2.5 cm of sterile aquarium stones and 24 L of tap water. A control tank with 20 turtles that were found to be excreting *Salmonella* was set up in an adjacent room. The aquarium was a 40-gallon (151.4 L) glass tank that included a Tetra Whisper EX45 water circulation pump (240 gph).

Water from each aquarium was sampled for *Salmonella* once a month for 12 months (Jan 2009–Jan 2010) following the methods detailed below. After taking water samples, all the water from the aquarium tanks was siphoned out and replaced with fresh tap water. With each water change, the carbon bio-bag within the water pump was also replaced.

Salmonella *assays.*—*Salmonella* has been detected from various types of samples after incubation in an enrichment broth and the use of a polymerase chain reaction (PCR) method (Aabo et al. 1995; Bennet et al. 1998; Chiu and Ou 1996; Lin and Tsen 1999; Soumet et al. 1999; Stone et al. 1994). To ensure *Salmonella* detection, we inoculated our samples in two enrichment broths, tetrationate broth (TTB) and selenite cysteine broth (SCB). Samples of 1 ml of water from each aquarium were inoculated into two tubes containing 7 ml TTB and two tubes containing 7 ml SCB. Inoculated SCB tubes were incubated for 24 hours and inoculated TTB tubes were incubated for 48 hours, both at 37°C. Cells from 1 ml of each enrichment broth culture were concentrated by centrifugation (14000 × g) for 5 minutes in a sterile 1.5 ml microcentrifuge tube. The cell pellets were suspended in 100 µl of 5% (w/v) Chelex 100 (Bio-Rad Laboratories) and bacterial chromosomal DNA was released by thermal lysis by incubation at 95° C for 5 minutes followed by 5 minutes on ice. This heat treatment was repeated and then the cell debris was removed by centrifugation (14000 × g) for 2 minutes. The *Salmonella* DNA was detected by PCR amplification with two *Salmonella*-specific primers that amplify unique DNA fragments of defined size (see below). We confirmed that the DNA preparation contained amplifiable bacterial DNA by including a PCR primer pair to a highly conserved region of the 16S ribosomal RNA genes of bacteria. PCR DNA fragments were revealed by agarose gel electrophoresis (see below). Hereafter, we will call this assay the *Salmonella* PCR method.

Primers and PCR conditions.—*Salmonella*-specific primers 139 and 141 were described by Rahn et al. (1992) and have the following nucleotide sequences based on the *invA* gene of *Salmonella*: 5' GTGAAATTATCGCCACGTTCGGGCAA-3' and 5' TCATCGCACCGTCAAAGGAACC-3', respectively. They allow amplification of a 285 bp PCR product from *Salmonella* DNA.

Salmonella-specific primers STM3098F1 and STM3098R2 were described by Kim et al. (2006) and have the following nucleotide sequences: 5' TTTGGCGGCGCAGGCGATTC-3' and 5' GCCTCCGCCTCATCAATCCG-3', respectively. It was demonstrated that this primer pair from a putative transcription regulator was *Salmonella*-specific and gives a 423-bp PCR amplified band in all subspecies of *Salmonella enterica* (I, II, IIIa, IIIb, IV, V, and VI). Most infections in endothermic animals are caused by subsp. I. In the wild ectotherms such as turtles contain primarily *S. enteric*a subspecies IIIa (*S. enterica* subsp. *arizonae*) and IIIb (*S. enterica* subsp. *diarizonae*; Diaz et al. 2006; Hopkins et al. 2009; Schroter et al. 2004).

For confirmation that DNA template preparations contained amplifiable bacterial DNA, primers to a conserved region of the 16S ribosomal RNA genes of all bacteria, rrs1 (5' TAACACATGCAAGTCGAACG-3') and rrs2 (5' CCCATTGTGCAATATTCCCC-3'), were used (Vliegenthart et al. 1990). These primers give a PCR amplified band of approximately 330 bp.

All primers were prepared as 20 µM solutions. The 25-µl PCR reaction mixture contained 2.5-µl template, 12.5 µl Go Taq Green Master Mix (Promega), 0.5 µl of each of the *invA* primers and STM3098 primers, 0.25 µl of each of the 16S rRNA gene primers, and deionized sterile water. PCR incubation was performed using Perkin-Elmer GeneAmp PCR system 2400. The cycle conditions were as follows: an initial incubation at 94°C for 5 minutes followed by 25 cycles of denaturation at 94°C for 1 minute, primer annealing at 53°C for 2 minutes, and primer extension at 72°C for 3 minutes. Following the last cycle they were incubated at 4°C.

After PCR amplification, 10 µl of each reaction was separated by electrophoresis on a 1.9% agarose (3:1 agarose from AMRESCO) with 0.5 µg/ml ethidium bromide (ETBr). The assay products were run for 45 minutes at 12.5 volts/cm^2 in TBE buffer (89 mM Tris, 89 mM borate, 2 mM EDTA, pH 8.0) also containing 0.5 µg/ml ETBr. The DNA bands were visualized under UV light and digitally imaged with a Strategene's Eagle Eye II.

Necropsies.— Necropsies were performed to demonstrate a 1:1 correlation between non-excretors and non-carriers. Eight "*Salmonella*-free" turtles (two turtles from each aquarium) and two turtles from the positive control tank were necropsied. The turtles were euthanized with an intracardia injection of Beuthanasia using 0.05 ml/turtle. Five turtles were necropsied on 1 July 2010, two from Tank A, two from Tank B, and one from Tank C. Five turtles were necropsied on 9 July 2010, one from Tank C, two from Tank D, and two from the positive control tank. Tissue samples from blood, an upper intestine sample containing throat, stomach and small intestine, and a lower intestine sample containing large intestine and rectum were analyzed for *Salmonella*. These tissue samples were put into 10 ml preenrichment broth, Difco lactose broth (Iazdjoo et al.1987). Lactose broth was used to enable us to dispense equal amounts of material into the enrichment broths. After 24 hrs at 37°C, 1 ml was used to inoculate each tube of enrichment broth (two tubes SCB and two tubes TTB) and tested for *Salmonella* as described above.

Results

During the 12 months of the study no *Salmonella* was detected from the water of the *Salmonella*-free turtle tanks (Table 1). A representative agarose gel from month seven analysis is shown in Fig. 1. Water from the control tank with the *Salmonella*-excreting turtles was positive (agarose gel exhibited the 3 expected PCR fragments) until the last two sample months (Table 1). The *Salmonella*-free turtle tanks exhibited only the approximate 330-bp ribosomal RNA product (rrs), which indicated the presence of bacterial DNA but not *Salmonella* DNA.

Salmonella was not detected by PCR assay from any necropsied tissue in 120 different enrichment cultures (ten turtles, three tissue samples from each turtle, two tubes TTB and two tubes SCB for each tissue sample). Two additional turtles of approximately the same age that were excreting *Salmonella* as part of another study were necropsied because the turtles from the positive control group were negative. *Salmonella* was cultured from the lower intestine-large intestine sample of these turtles. These additional necropsies validated our dissection techniques for the detection of *Salmonella*.

Discussion

In this study we demonstrated that 40 *Salmonella*-free turtles remained *Salmonella*-free for over a year. The turtle hatchlings were divided into four aquarium tanks and the water was tested for *Salmonella* once a month before each water change. We used duplicate cultures from two different enrichment broths to prepare DNA templates for the PCR analysis and used two sets of *Salmonella*-specific primers. This PCR analysis should have detected *Salmonella* even if just one of the 40 turtles began to excrete *Salmonella*. Our results demonstrated that these turtles will not eventually begin to actively shed *Salmonella*. First, 12 months should be long enough to expect that if the turtles carried *Salmonella*, it would be found (Kaufmann et al. 1967). Second, two turtles from each aquarium tank were necropsied and again *Salmonella* could not be detected by PCR in blood and upper and lower intestinal samples. If these turtles had established bacterial flora with *Salmonella*, then we should have detected *Salmonella* in their intestines. Only two turtles from the *Salmonella*-positive tank were necropsied because we expected to find *Salmonella* in their intestines. Since the *Salmonella*-free turtles already have an established bacterial flora in their intestines, we expected they would not easily become carriers of *Salmonella*. In support are the investigations by Pasmans et al. (2002), who showed that *Salmonella enterica* subsp. *Muenchen* only colonized the mucosal lining of the intestine of orally-infected *T. scripta scripta*. *Salmonella* invasion of the intestinal wall and the colonization of internal organs were not observed. In their study, *Salmonella* was isolatable from the large intestine for only eight days.

Our results suggest that if a *Salmonella*-free turtle is acquired from a Louisiana turtle farm and the appropriate environment is provided, it is likely to remain *Salmonella*-free. We feel that an appropriate environment should include an aquarium tank with a water recirculator and the turtles being fed only commercial pet food. The possibility of acquiring *Salmonella* is more likely in free-ranging turtles found in pond and lake environments where the turtles are in constant contact with *Salmonella*-contaminated water, rather than a controlled environment. However, many studies have reported a low prevalence of *Salmonella* in free-ranging chelonians (Harwood et al. 1999, 5%; Lockhart

et al. 2008, 5%; Readel et al. 2008, 0%; Richards et al. 2004, 0%; Saelinger et al. 2006, 0%). In a recent paper by Readel et al. (2010), in which the possibility that the turtles may harbor but not actively shed *Salmonella* was investigated by performing intestinal mucosal scrapings of adult free-ranging red-eared sliders in ponds in Illinois, *Salmonella* was detected in only 8 of 73 (11%) adult turtles analyzed. However, other studies have found environments where the percentage of turtles harboring *Salmonella* have been higher. For example, Gaertner et al. (2008b) found 8 out of 21 Red-eared Sliders (38%) had *Salmonella* and another study performed by the same group found that 51% of free-ranging turtles were carriers of *Salmonella* (Gaertner et al. 2008a). The importance of our study is that *Salmonella*-free turtles within a proper environment with limited or no exposure to *Salmonella* remained *Salmonella*-free.

The inability to detect *Salmonella* after ten months in our positive control was not expected. Transient shedding of *Salmonella* was documented in turtles by Kaufmann et al. (1967). They found ten groups of turtles were excreting *Salmonella* nine months after hatching, but only six groups excreted *Salmonella* a full year after hatching. Kaufmann kept turtles separated in shallow pans. Otis and Behler (1973) investigated turtles in the New York Zoological Park (Bronx Zoo) for *Salmonella*. They observed that turtles in tanks with water recirculators were found to not harbor *Salmonella* whereas community tanks often harbored *Salmonella*. They believed that placing infected turtles in tanks with water recirculators may clear the turtles of *Salmonella*. In our study, the positive control turtles were in an aquarium equipped with a water recirculator that may have facilitated the loss of *Salmonella*. In a related study, Mitchell et al. (2005), evaluating the efficiency of Baquacil to suppress *Salmonella* in aquatic turtles, could not detect *Salmonella* in 20% of their initial excreting controls after one month by both water sampling and turtle necropsy. A possibility proposed by Mitchell et al. (2005) is that the turtles could have "self-cleared or not remained colonized" with *Salmonella*.

Poor environmental conditions and other causes of physiological stress likely contribute to whether turtles remain carriers of *Salmonella*. In this study, turtles were housed in a large aquarium environment, with plenty of space and enough water to swim and to be active. Water was filtered and changed regularly and the turtles were fed a healthful diet. Future studies are needed to determine if these environmental conditions allow for the suppression or elimination of *Salmonella* in *Salmonella*-excreting turtles.

Acknowledgments.—We thank Eric Achberger for helpful comments on the manuscript. We thank Wes Baumgartner from Louisiana State University School of Veterinary Medicine for performing the turtle necropsies. We thank undergraduate student Aaron Gardner for laboratory assistance. This research was supported by the Louisiana Department of Agriculture. This study was conducted in accordance with the regulations specified by the Louisiana State University Institutional Animal Care and Use Committee Protocol Number AE2010-05.

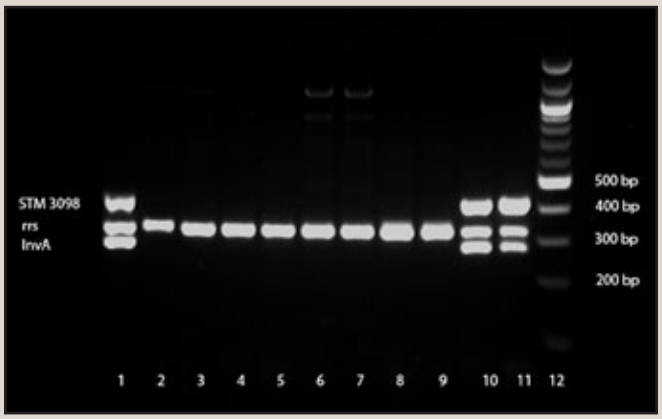

FIG. 1. Representative agarose gel electrophoresis of PCR products of the samples from month seven. On this gel all samples were from independent TTB enrichments of tank water. Positive lanes have three PCR products, the 423-bp STM3098 product, approximate 330-bp product for ribosomal RNA (rrs) genes, and the 285-bp *Salmonella inv*A product. Negative lanes only have the rrs fragment. Lane 1, Control *Salmonella* DNA. Lanes 2 and 3 are from tank A. Lanes 4 and 5 are from tank B. Lanes 6 and 7 are from tank C. Lanes 8 and 9 are from tank D. Lanes 10 and 11 are from *Salmonella*-positive control turtle tank. Lane 12 is a 100-bp ladder (New England Biolabs); the thick bands are 500 and 1000 bp.

TABLE 1. Presence of *Salmonella* in the water of turtles' tanks. Every sample involved two SCB and TTB enrichments before being tested for *Salmonella* by the PCR assay. Water samples from which *Salmonella* was detected in any of the enrichment cultures are scored positive. "Negative" indicates that both *Salmonella* primer products (invA and STM3098) were not detected but ribosomal rrs primer product was detected in the enrichment samples.

An Old World Skink, *Chalcides ocellatus*, with a Long History of Anthropogenically Assisted Dispersal, Now Established in Mesa, Arizona, USA

The Ocellated Skink, *Chalcides ocellatus*, is native to northern Africa, the Middle East and the Mediterranean (Pasteur 1981; Schleich et al. 1996). It occurs in a diverse array of habitats including: "…sand and gravel deserts, agricultural lands, gardens, and piles of refuse along the Mediterranean coast…" (Attum et al 2007). Using genetic analyses, Kornilios et al. (2010) argued that this lizard has colonized islands throughout the central and eastern Mediterranean in part due to anthropogenic assistance over the past three thousand years. Caputo et al. (1997) suggested that populations of *C. ocellatus* in southern Italy and nearby islands (Sicily, Sardinia), as well as its discontinuous range across Greece and various islands of the Aegean Sea, are best explained by a long history of colonization via anthropogenic facilitation. More recently, Kraus (2009) documented that *C. ocellatus* has been introduced to France and Great Britain, and established in Italy. With respect to the New World, Krysko et al. (2011) documented its presence in Broward and Pasco counties, Florida, USA. They found that a local reptile dealer in Mirimar, Florida, purchased *C. ocellatus* collected from local areas for resale in the pet trade (Krysko et al. 2011). It appears that *C. ocellatus,* like a number of squamates (e.g., gekkonids, lacertids, and iguanids), has expanded its range due in part to its ability to thrive in close proximity to humans and their habitations in relatively warm regions on several continents. Here we report on an established, actively reproducing population of *C. ocellatus* in a suburban area located in the arid Sonoran Desert Biome, near Phoenix, Arizona, USA.

Kornilios et al. (2010) argued that, as a relatively generalized omnivore with ovoviviparous reproduction, *C. ocellatus* is a good candidate for colonization following transportation in soil with plants, or via other means associated with human activities. Attum et al. (2007) suggested that with respect to morphology, *C. ocellatus* is a generalized skink in comparison to relatives specialized for sandy habitats, and unlike its sand-dwelling relatives, typically escapes to vegetation in response to the approach of predators. Though a number of the recently established populations of *C. ocellatus* have been documented in relatively mesic environments, with ample vegetation associated with anthropogenically altered habitats (e.g., Caputo et al. 1997; Krysko et al. 2011), they have not been documented in arid regions of the New World. Given its occurrence in relatively arid habitats in the Old World, and propensity to colonize anthropogenically impacted landscapes, the success of *C. ocellatus* in the southwestern USA is potentially of great interest.

One of us (JG) first observed *C. ocellatus* in a relatively high density housing area of Mesa, Maricopa Co., Arizona, USA (111.852°W, 33.361°N; NAD 1927), in 2007; in 2011, another of the authors (RB), independently discovered individuals (Fig. 1) in the same neighborhood, and began to canvass the area to determine the extent of the distribution. The results we present here are of two kinds: data on individual skinks collected by one of the authors during 2011 and early 2012, and reports on skinks by residents in the neighborhood in response to either door to door interviews or "information wanted flyers" distributed in the fall of 2011. Person to person interview validity during door to door surveys and in follow-up interviews with residents that responded to flyers was established by only recording those observations in which the occupant was familiar with lizards in general, and had lived in the residence for a minimum of one year, or recognized *C. ocellatus* from a photograph. During interviews, several residents volunteered "oh, those skinks" before they were even provided the photograph of the lizard (no other skinks occur within ~ 50 km of Mesa; Brennan and Holycross 2006).

Canvassing of the neighborhood revealed that two different residents were confident they first observed *C. ocellatus* during 2001 (both within 0.5 km of the 2007 observation of JG). Residents reported *C. ocellatus* from potted plants, block walls, larger planters, and shrubbery, but also from comparatively barren micro-sites, such as the interiors of garages and storerooms. In sum, 18 different residents spread across an area of ~ 30 ha reported the presence of one or more individuals of one or more size classes over the past decade (Fig. 2). During 2011–2012, we collected a total of 20 individuals within roughly 15 ha of the same general area, which ranged in size from 68 to 118 mm SVL (mean ± SE: 91.0 ± 3.21 mm), with an apparent bimodal size class distribution (most individuals were ~ 85 or 115 mm SVL; total length ~160–230 mm). This mean SVL is at the upper end of that documented for a number of Old World populations of *C. ocellatus* (mean = 79–94 mm for six samples; see review in Greenbaum et al. 2006). It is important to note that these individuals were collected during a particularly dry fall and winter, prior to the onset of warm temperatures and presumably higher levels of activity.

The cumulative distribution of sightings and collected individuals yields an area of occupation of ~ 30 ha. Because two size classes have been observed over more than ten years, including many sub-adults (not represented in the size data above; lizards ~ 50 SVL were often observed, but escaped capture), it is clear that reproduction is occurring locally, and thus a "stage 3" level introduction (Emerton and Howard 2008) has been attained for this species in Arizona: a naturalized population is established, and capable of spreading in the immediate area without

assistance. Although assessment of size estimates by residents is potentially problematic, at least two residents reported having seen much larger individuals (~ 250 mm TL, the upper end of the size distribution of *C. ocellatus*; Mateo et al. 1995).

Given their popularity in the pet trade, perhaps the simplest explanation for this colonization by *C. ocellatus* is the result of herpetocultural exchange including accidental or intentional release. If *C. ocellatus* arrived, as they reportedly did in Naples (Caputo 1997) via ornamental vegetation nursery stock, they may be arriving intermittently, or transported elsewhere via landscape management practices including debris removal from resident yards in the area of establishment. In addition to the landscape management assisted transport scenario described above, as area residents move, *C. ocellatus* will also have the opportunity to relocate via ornamental vegetation nursery stock, storage boxes, and other items. *Chalcides ocellatus* is the third saurian to become established in Arizona (*Ctenosaura macrolopha* and *Hemidactylus turcicus*; Brennan and Holycross 2006). Our observations highlight the establishment of *C. ocellatus* in a relatively mesic island of urban habitat surrounded by the xeric Sonoran Desert in Arizona. It is noteworthy that the only widespread lizards inhabiting urban areas of the Sonoran Desert are arboreal or scansorial (*Urosaurus ornatus* and *Hemidactylus turcicus*), which may be less susceptible to predation by house cats; *C. ocellatus* represents the only relatively large, ground-dwelling saurian in this urbanized environment.

The notion that biological communities can be negatively impacted by the successful colonization of exotic species is a widely held tenet of conservation biology, though the costs and the benefits of removing exotics is open to debate (see reviews in Davis et al. 2011 and Simberloff 2011). While any introduced species warrants monitoring, understanding the means by which exotic organisms become introduced and established in novel communities, including the timeline during the early stages of establishment, should be afforded careful consideration.

Acknowledgments.—We thank George Bradley, Petros Lymberakis, and Panagiotis Kornilios for their assistance and support; definitive identification of specimens from Mesa was provided by P. Kornilios. This work was conducted under IACUC approval (BKS) and with support of the Arizona Game and Fish Department (scientific collecting permits to BKS). We thank the many residents of Mesa that assisted with our observations, allowed access to their yards, and facilitated our research efforts; thanks as well to Tom Jones, Rob Lovich, and an anonymous reviewer for comments on the manuscript. A specimen has been accessioned in UA herpetology collection (UAZ 57401), and BKS # 2046-2049 are awaiting accession in the ASU Vertebrate Collection.

Northwestern Salamanders (*Ambystoma gracile*) in Mountain Lakes: Record Oviposition Depths Among Salamanders

Oviposition timing, behaviors, and microhabitats of ambystomatid salamanders vary considerably (Egan and Paton 2004; Figiel and Semlitsch 1995; Howard and Wallace 1985; MacCracken 2007). Regardless of species, however, females typically oviposit using sites conducive to embryo development and survival. For example, the results of an experiment by Figiel and Semlitsch (1995) on *Ambystoma opacum* (Marbled Salamander) oviposition indicated that females actively selected sites that were under grass clumps in wet versus dry treatments, and surmised that environmental conditions such as humidity, moisture, and temperature contributed to their results. Other factors associated with ambystomatid oviposition and embryo survival include water temperature (Anderson 1972; Brown 1976), dissolved oxygen concentration (Petranka et al. 1982; Sacerdote and King 2009), oviposition depth (Dougherty et al. 2005; Egan and Paton 2004), and oviposition attachment structures such as woody vegetation (McCracken 2007; Nussbaum et al. 1983). Resetarits (1996), in creating a model of oviposition site selection for anuran amphibians, hypothesized that oviparous organisms were also capable of modifying oviposition behavior and site selection to accommodate varying habitat conditions and to minimize potential negative effects of environmental stressors. Kats and Sih (1992), investigating the oviposition of *Ambystoma barbouri* (Streamside Salamander) in pools of a Kentucky stream, found that females preferred pools without predatory *Lepomis cyanellus* (Green Sunfish), and that the number of egg masses present in a pool historically containing fish increased significantly the year after fish had been extirpated from the pool. Palen et al. (2005) determined that *Ambystoma gracile* (Northwestern Salamander) and *Ambystoma macrodactylum* (Long-toed Salamander) eggs were deposited either at increased depth or in full shaded habitats, respectively, as water transperancy to UV-B radiation increased.

Ambystoma gracile is a Pacific Northwest (USA and Canada) species that breeds in permanent ponds and lakes from sea level to about 2000 m elevation (Corkran and Thoms 1996; Leonard et al. 1993; Richter 2005). Egg masses are usually affixed to stems of emergent–submergent vegetation or the branches of submerged woody debris. Reported depths for *A. gracile* egg mass oviposition range from just below the water surface to 2 m deep (Table 1). Here we describe *A. gracile* oviposition in a montane lake in Mount Rainier National Park (MORA), Washington, USA, which is substantially deeper than previous reports.

Methods.—On 23–24 July 2003 and 12 July 2005, we surveyed 4 lakes at MORA for *A. gracile* egg masses (Table 1). A total of 276 egg masses were observed in the 4 lakes, all attached to branches of submerged fir and hemlock trees (Fig. 1). In 2003, Dick, Harry, and Sunrise Lakes were surveyed during daytime snorkel surveys, and depths from the lake surface to the top of each observed egg mass were measured using a meter tape. In 2005, Upper Palisades Lake (Fig. 2) was surveyed by two SCUBA divers, and egg mass depths were measured using a Suunto Favor Air Lux Dive Computer with depth gauge. During the period 1996–2004, 12 daytime and 2 nighttime shallow littoral snorkel surveys for locating *A. gracile* egg masses and larvae were also conducted in Upper Palisades Lake. Larvae were observed during these surveys but egg masses were not.

Dick, Harry, and Sunrise Lakes have extensive and relatively shallow littoral zones which slope gradually to a flat bottom (maximum depths = 2.5, 4.2, and 7 m, respectively). The littoral zones contain abundant sunken logs and large woody debris, and some emergent–submergent vegetation. In 2003, the 3 lakes were fishless, although Harry and Sunrise Lakes were historically stocked with non-native salmonids (Harry = 3 times between 1926 to 1951; Sunrise = 21 times between 1926 to 1971; MORA, unpubl. stocking records). All fish were removed from Harry Lake using gill nets during the summers of 1996 through 1998, and the absence of fish from Sunrise Lake was determined during the same period by angling, using gill nets, and observation during snorkel surveys. Although Dick Lake was never stocked, gill nets were set in the lake in 1996 to determine the absence of fish and subsequent snorkel surveys were used to further document fish absence.

Upper Palisades Lake has minimal littoral habitat primarily on a relatively shallow shelf (variable maximum depth = ~1–3 m) just beyond the mouth of a stream flowing into the lake, and the lake slopes steeply on all sides beyond the shelf to a maximum depth of 15.3 m (Fig. 2). There is no emergent–submergent vegetation in the littoral zone, and accumulations of large woody debris are present predominantly at depths >3m, due, in part, to the steeply sloping perimeter and bowl-shaped bathymetry of the lake (Fig. 2). Gill nets were used to remove Eastern Brook Trout (*Salvelinus fontinalis*) from Upper Palisades Lake in 1996. Subsequent gill netting efforts and snorkel surveys documented the continued absence of fish from the lake, which was fishless in 2005. The lake had previously been stocked 7 times between 1961 and 1971 (MORA, unpubl. stocking records). The *A. gracile* adults in Upper Palisades Lake are predominantly neotenes or gilled-adults. Frequency of this life-history stage increases with

elevation, and it is uncommon for individuals to transform to the terrestrial life stage in Pacific Northwest mountain lakes (Eagleson 1976; Efford and Mathias 1969; Snyder 1956; Taylor 1983). In the decade (1996–2005) that we have conducted research at MORA, we have rarely observed transformed *A. gracile* adults while snorkeling or hiking in the park. The *A. gracile* adults in Dick, Harry, and Sunrise Lakes are also predominantly neotenic.

We compared oviposition depths among the 4 MORA lakes using one-way ANOVA with a Bonferroni Multiple Comparison Test. Significance was set at $P = 0.0125$. For further comparison, we also summarized data on *A. gracile* oviposition from 6 additional sources (Table 1).

Results and Discussion.—The Upper Palisades Lake mean oviposition depth (4.9 m) was significantly deeper (F-ratio = 434.7, $df = 3$, $P < 0.0001$) than the mean oviposition depths in the other 3 MORA lakes (range = 1.0–1.2 m) (Table 1). The range of Upper Palisades Lake oviposition depths (3.1–9.8 m) was also considerably deeper than in Dick, Harry, and Sunrise Lakes (0.23–2.4 m), and the range of depths reported by the 6 additional sources (0–1.5 m) (Table 1). In contrast, the oviposition depth ranges for Dick, Harry, and Sunrise Lakes were comparable to the range of depths reported by the other sources (Table 1), although the mean maximum oviposition depth (2.13 m) for the 3 MORA lakes was just over 1 m deeper than the mean maximum oviposition depth (0.96 m) we calculated for the other sources. The deepest egg mass in Upper Palisades Lake was observed at 9.8 m, which extends the reported record oviposition depth for *A. gracile* by just over 7 m (i.e., 2.4 m in Sunrise Lake).

Ambystoma gracile egg masses are known to contain a symbiotic green algae whose presence within egg capsules becomes more apparent as the masses age (Nussbaum et al. 1983; Petranka 1998; Richter 2005). It has been documented that the presence of this algae in *Ambystoma* spp. egg capsules serves to enhance the development of embryos and contributes to hatching at earlier stages of development or over a shorter period of time (Gilbert 1944; Tattersall and Spiegelaar 2008). However, eggs in masses in which the algae is reduced in presence or absent are not necessarily negatively affected. The results of a recent study by Kerney et al. (2011) also produced evidence that the presence of green algae in *Ambystoma maculatum* (Spotted Salamander) egg masses is endosymbiotic, indicating that the algae is carried and transmitted by ovipositing adults. This finding, however, has not been documented for other species of *Ambystoma*. The egg masses that we have observed in the 4 MORA lakes are generally deficient in the presence of green algae, although some egg capsules within a mass contain algae as the mass ages. We speculate that this reduced presence of algae may be due, in part, to: 1) the depths at which egg masses are deposited in the MORA lakes (for example, Tattersall and Spiegelaar (2008) found that the algal content of *A. maculatum* egg masses was negatively correlated with oviposition depth); 2) the use of attachment sites that shade and restrict the amount of available light reaching an egg mass for promoting algal growth; or 3) the possibility that the presence of algae in *A. gracile* egg masses is not or is only minimally endosymbiotic. More research will be required to definitively determine why the presence of green algae is reduced in the *A. gracile* egg masses of the 4 MORA lakes.

During the 12 July 2005 SCUBA survey, we observed numerous *A. gracile* larvae at depths of 6 and 14 m on the bottom substrate of Upper Palisades Lake; and on 1 September 2005 we observed 93 larvae (ca. 10 to >90 mm total length) in four 25-m transects during a daytime snorkel survey of the Upper Palisades

TABLE 1. Comparison of *Ambystoma gracile* egg mass depths in the Pacific Northwest, USA and Canada (MORA = Mount Rainier National Park; nr = not reported; standard errors are in parentheses).

Lake littoral zone. The presence of these larvae indicates that embryos from at least some of the deeply placed egg masses survive to hatching, and eventually develop into reproductively mature adults. Two water quality parameters, dissolved oxygen concentration [DO] and temperature, which are critical to amphibian embryonic development and hatching, are not outside of critical limits for *A. gracile* in Upper Palisades Lake. Although we did not measure [DO] in the lake in 2005, measurements in July 1993–1994 (MORA, unpubl. data) and August 2008–2009 (Anne Weekes, USGS, unpubl. data) indicate that [DO] is high and not limiting at the range of oviposition depths in the lake (1993–1994 ranges: 3 m = 9.1–10.0 mg/L, 5 m = 9.9–10.8 mg/L, 10 m = 10.0–11.5 mg/L; 2008–2009: 3 m = 8.4–9.1 mg/L, 5 m = 8.5–9.1 mg/L, 10 m = 9.4–11.5 mg/L). Similarly, near bottom [DO] in Dick (1.5–2 m mean = 6.4 mg/L; 1994, 1996), Harry (3 m mean = 7.2 mg/L; 1989, 1994), and Sunrise (5.5–6.5 m mean = 7.9 mg/L; 1988, 1994, 2004–2005) Lakes are at concentrations suitable for *A. gracile*. Water temperature also was not limiting. Anderson (1972) and Brown (1976), in separate laboratory studies, determined that development of *A. gracile* embryos proceeds normally at water temperatures of 6–20°C, with time-to-hatching inversely related to temperature (89 to 53 d at 7 to 8°C, respectively; Brown 1976). The water temperature on 12 July 2005 in Upper Palisades Lake, at depths of 4.6 (just above the mean depth of oviposition) to 14 m, was 7.8°C. We speculate that at this temperature it can take up to 90 d or more for embryos to develop and hatch in the lake. Near bottom water temperatures in Dick (1.5–2.5 m mean = 15.6°C; 1989, 1994, 1996), Harry (3 m mean = 15°C; 1989, 1994), and Sunrise (5.5–6.5 m mean = 15.8°C; 1988, 1994, 2004–2005) Lakes were comparatively warmer than in Upper Palisades Lake, and embryos would most likely develop and hatch within a minimum of 17 to as many as 46 d in the 3 lakes (Brown 1976).

The *A. gracile* egg masses we found in Upper Palisades Lake were at much greater depths than is considered typical for this species. These were the deepest depths that we could find documented in the literature for any *Ambystoma* species or other pond-breeding salamander group. We suspect that this pattern of oviposition in Upper Palisades Lake is primarily a reflection of the lack of available attachment structures in the shallower areas of the lake, and the relatively deep occurrence of preferred oviposition braces and environmental conditions at those depths conducive to successful embryo development and survival. Additional deep mountain lakes inhabited by *A. gracile* should be surveyed to determine if oviposition at these deeper depths is more common than is presently thought.

Acknowledgments.—We thank Mark Buktenica and Scott Girdner (U.S. National Park Service, Crater Lake National Park) for their assistance and support as SCUBA divers for the egg mass ovipositon surveys; the Aquatic Resources staff at Mount Rainier National Park for their logistical assistance and support; Anne Weekes (U.S. Geological Survey, Forest and Rangeland Ecosystem Science Center) for her contribution of dissolved oxygen data; and Wendy Palen (Simon Fraser University) for her contribution of *A. gracile* egg mass oviposition depth data. We also thank Glenn Tattersall and an anonymous reviewer for their comments and suggestions that helped improve the manuscript. This study was conducted under the auspices of NPS permits and the authors have complied with all applicable Institutional Animal Care and Use Committee guidelines, ACUP # 2763. Any use of trade, product, or firm names is for descriptive purposes only and does not imply endorsement by the U.S. Government.

Rattlesnakes of the *Crotalus mitchellii* (Speckled Rattlesnake) complex have been reported from 12 islands in the western Sea of Cortés, Mexico (Grismer 2002; Murphy and Aguirre-Léon 2002). Mean body size varies considerably across these island populations, and *C. mitchellii* is unusual among viperids in exhibiting both insular gigantism and dwarfism (Boback 2003). Dwarfism is common in insular populations, while gigantism is known only from Ángel de la Guarda Island. Body size shifts relative to mainland populations may be partly influenced by resource availability, as body size in *C. mitchellii* is strongly correlated with island area (Meik et al. 2010). Shifts in diet composition are also often implicated in body size divergence between mainland and island snakes (Boback 2003; Case 1978); however, there are few data comparing diets between insular and mainland populations (but see Forsman 1991; Madsen and Shine 1993). Klauber (1949) reported that dwarfed Speckled Rattlesnakes from El Muerto Island had eaten both side-blotched lizards (*Uta lowei*) and Banded Rock Lizards (*Petrosaurus mearnsi*). Case (2002) and Grismer (2002) speculated that giant Speckled Rattlesnakes from Ángel de La Guarda Island eat mostly Desert Woodrats (*Neotoma lepida*) and Spiny Chuckwallas (*Sauromalus hispidus*), herbivorous lizards that attain weights of over a kilogram. On a drizzly day in April 1981, Case (2002) encountered two Speckled Rattlesnakes on Ángel de la Guarda Island that were each in

the process of swallowing Spiny Chuckwallas. Other than these anecdotal accounts, data on the diets of insular Speckled Rattlesnake populations are unavailable.

Here we report new data on activity, body size variation, and diet in insular Speckled Rattlesnakes from five islands in the northwestern Sea of Cortés: El Muerto, Smith, Piojo, Cabeza de Caballo, and Ángel de la Guarda. Of these, Smith, Piojo, and Cabeza de Caballo are nearshore islands in Los Angeles Bay, while Ángel de la Guarda is located to the east of Los Angeles Bay, and El Muerto is situated approximately 100 km to the northwest of Ángel de la Guarda (Fig. 1). Although two recent checklists of the insular herpetofauna of Baja California report *C. mitchellii* from Cabeza de Caballo Island (Grismer 2002; Murphy and Aguirre-Léon 2002), until now no voucher specimens or photographs have been deposited in collections in the United States or Mexico.

Materials and methods.—We collected voucher specimens of Speckled Rattlesnakes from El Muerto Island on 23 May 2006, Ángel de la Guarda Island on 25 May 2006, and from Cabeza de Caballo, Piojo, and Smith islands between 17–20 March 2010. Snakes were euthanized within 12 h of capture by chloretone injection to the heart, preserved in 10% formalin, and later transferred to 70% ethanol for long-term storage. We measured snout–vent length (SVL) and tail length with a metric ruler, and head length with a digital caliper. We used rattle segment count as a crude indicator of snake ontogeny because rattle segments of equal width indicate asymptotic growth has been reached (Klauber 1940); only adult snakes were included in estimates of mean SVL. Data on prey items were obtained from feces or by direct examination of gastrointestinal tracts of preserved specimens. We deposited all material at the collections of the Museo de Zoología, Facultad de Ciencias (MZFC), Universidad Autónoma de México, and The Amphibian and Reptile Diversity Research Center at the University of Texas at Arlington (UTA) under the following accession numbers: MZFC 24988–24989 (Ángel de la Guarda); MZFC 26407–409, UTA R-59763–765 (Cabeza de Caballo); MZFC 24984–86 (El Muerto); MZFC 26410–412, UTA R-59766–767 (Piojo); MZFC 26413, UTA R-59768–769 (Smith).

Meik et al. (2010) presented a correlation analysis of mean SVL of island populations as a function of island area; however, their analysis did not include rattlesnakes from Cabeza de Caballo Island. We updated this analysis by adding data on snakes from this island population, as well as additional data for populations from Smith and Piojo islands.

Results and discussion.—Our observations of Speckled Rattlesnakes on both El Muerto (30.087°N 114.541°W) and Ángel de la Guarda (29.170°N 113.332°W) islands are consistent with previous reports (Armstrong and Murphy 1979; Klauber 1949). We visited these islands on 23 and 25 May 2006, respectively, and daytime high temperatures were approximately 34°C. On El Muerto Island, we found three adult snakes within two hours of dusk (two males and a female between 2100 and 2200 h). We encountered one male at about 20 m above sea level on the rocky slope of a steep canyon; the other two snakes were found moving in the upper intertidal zone. Similar to reports provided by Klauber (1949) and Armstrong and Murphy (1979), rattlesnakes from El Muerto were nervous and rattled vigorously at our approach. When collected, these snakes thrashed and struck repeatedly at snake tongs. Similar behavior prompted C. H. Lowe to speculate (in Klauber 1949) that snakes of this population likely have important avian predators, possibly Ospreys (*Pandion haliaetus*) or Peregrine Falcons (*Falco peregrinus*), which are known from the island. We collected two adult male rattlesnakes on Ángel de la Guarda Island, one at dusk, and one approximately an hour and a half later (2130 h). The first individual was found coiled beneath a large agave on the gentle slope of a broad valley approximately 1 km from the sea. The second snake was crossing a sandy wash about 150 m from the shoreline. In contrast to the behavior of snakes from El Muerto, snakes from Ángel de la Guarda were docile. These snakes did not adopt defensive postures or strike, and rattled only briefly in one or two-second bouts.

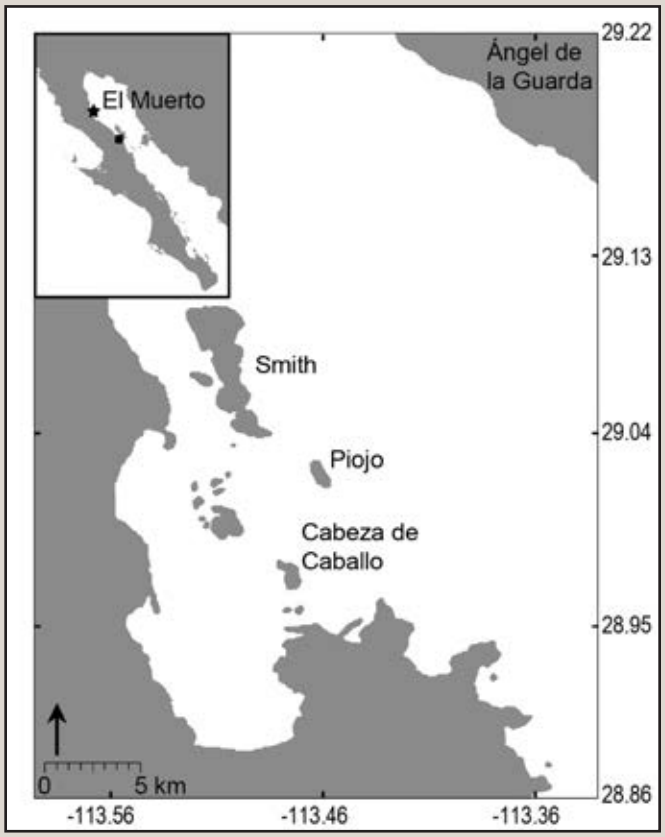

FIG. 1. Map of Los Angeles Bay, and northern Sea of Cortés (inset), showing locations of islands visited during this study (El Muerto, Ángel de la Guarda, Smith, Piojo, and Cabeza de Caballo). The square in the inset indicates the location of Los Angeles Bay within the Baja California Peninsula.

FIG. 2. Photograph of a Speckled Rattlesnake (*Crotalus mitchellii*; MZFC 26409), *in situ*, coiled between boulders on Cabeza de Caballo Island.

COLOR REPRODUCTION SUPPORTED BY THE THOMAS BEAUVAIS FUND

Situated at the southern end of the mouth of Los Angeles Bay, Cabeza de Caballo (28.973°N 113.479°W) is a small (0.77 km^2), steep island with extensive basaltic rock outcroppings. We visited the island between 17–18 March 2010 when overall conditions were cool and windy. All rattlesnakes were encountered during mid-morning and early afternoon hours (1000–1300 h) on 18 March except for an adult male that was active near the highest peak of the island at 2130 h on the night of 17 March (N = 6 total). Of the five snakes collected during the day, the first four were found coiled and exposed on the ground, abutted against boulders (Fig. 2). When disturbed, snakes rattled vigorously and retreated toward rock crevices over two meters from where they had been coiled. The position and posture of these rattlesnakes indicated they were likely both thermoregulating and waiting in ambush for passing prey.

On 18–19 March 2010, we visited Piojo Island (29.016°N, 113.464°W), the outermost island in Los Angeles Bay. Piojo consists of a rugged, plateau-like escarpment, and is sparsely vegetated compared with other major islands in the bay. The island serves as a rookery for Brown Pelicans (*Pelecanus occidentalis*), and most available woody debris has been incorporated into large nests concentrated on the floors of canyons and ravines that are less exposed to the high winds that pummel the island.

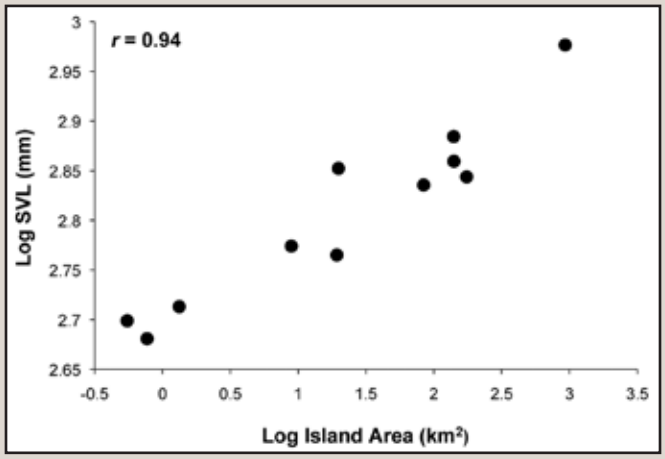

FIG. 3. Relationship between mean log snout–vent length (SVL) and log island area for populations of Speckled Rattlesnakes (*Crotalus mitchellii*) from the western Sea of Cortés, Mexico.

Seib (1978) first reported *C. mitchellii* from Piojo, and Grismer (2002) indicated that on the island *C. mitchellii* could be found beneath pelican nests. The night of 18 March was cool (ground temperature ca. 16°C) and windy; nonetheless, we encountered four rattlesnakes (two juveniles and two adults) active on the elevated flat plateau of the island (between 2030–2200 h). The following afternoon (ca. 1230 h), we found an adult female *C. mitchellii* basking in the intertidal zone of a large basalt finger that protruded into the sea from the northern beach. On the night of 19 March, we searched for Speckled Rattlesnakes on Smith Island (29.051°N 113.509°W), the largest and most topographically diverse island in Los Angeles Bay. We collected three individuals from rocky canyons of the island interior; each of these snakes revealed its presence by rattling.

Mean SVL of six rattlesnakes from Cabeza de Caballo was 479.5 ± 65 mm, the lowest mean SVL yet reported from an insular population of *C. mitchellii* (other populations range from 500 to 947.3 mm in mean SVL; Meik et al. 2010). Although our sample sizes for insular rattlesnake populations from Los Angeles Bay are relatively small (N = 8 for Smith, N = 10 for Piojo, N = 6 for Cabeza de Caballo), most specimens had long, broken rattle chains consisting of 8–11 segments of nearly equal width; therefore, we surmise that these snakes were mature adults. Furthermore, Meik et al. (2010) reported a female specimen of 360 mm SVL from Piojo Island that had enlarged follicles, indicating that reproductive maturity is attained at small sizes in these insular populations (Goldberg [2000] reported the smallest reproductive female in a sample of mainland *C. mitchellii* to be 552 mm SVL). The relationship between log island area and log mean SVL was significant ($r = 0.94$, $P < 0.0001$; Fig. 3), and the additional data improved the strength of the correlation coefficient by about 0.1 from that of a similar analysis presented by Meik et al. (2010).

Studies of insular snake populations have demonstrated that body size shifts may be influenced by adaptive evolution and phenotypic plasticity (Aubret and Shine 2009; Bronikowski 2000; Tanaka 2011)—presumably responses to island environmental regimes that include different resource availability and population densities, as well as differences in prey size distributions. Divergence in body size distributions between insular and mainland snakes may also result from simple differences in survivorship between populations (Hasegawa and Mori 2008; King 1989), which could be important for insular populations because they typically experience different predation regimes than do

TABLE 1. Prey items identified from digestive tracts and feces of insular Speckled Rattlesnakes (*Crotalus mitchellii*). Snout–vent length (SVL) is reported for each rattlesnake.

			Prey Items Recovered

populations from the mainland. High predation rates could have shifted body size distributions toward smaller size in populations of dwarfed rattlesnakes; however, terrestrial mammalian predators present on the mainland are absent on islands with dwarfed rattlesnakes. It is possible that certain avian predators may specialize on small insular rattlesnakes, which could select for the pugnacious behavior observed in these populations. The long rattle chains observed on small insular rattlesnakes from islands in Los Angeles Bay provides evidence that these snakes may be long-lived adults; thus, although predation may remain important for insular dwarfs, it seems that predation alone is not sufficient to have shifted the distribution of body sizes downward. Long-term mark-recapture studies that would provide estimates of survivorship are needed to partly test this hypothesis.

We recovered a total of 11 identifiable prey remains from the digestive tracts or feces of Speckled Rattlesnakes collected from islands in the Sea of Cortés (Table 1). A female specimen collected from El Muerto contained a wood warbler (*Dendroica* sp.) in its stomach, and an adult male from Piojo had consumed a large Deer Mouse (*Peromyscus maniculatus*); all other diet items were lizards. On islands in Los Angeles Bay, most larger snakes with prey remains had eaten juvenile Spiny Chuckwallas (*Sauromalus hispidus*); most smaller snakes had eaten Common Side-blotched Lizards (*Uta stansburiana*), and in one instance, a Peninsular Leaf-toed Gecko (*Phyllodactylus xanti*). Both juveniles collected from Piojo had eaten side-blotched lizards, and one of these snakes contained two lizards in its stomach. We found compacted vegetation (including twigs, seeds, and leaves) in the digestive tracts of each rattlesnake that had eaten a chuckwalla, and one such bolus of vegetation also contained several small lepidopteran larvae. We assume that these items were consumed by chuckwallas that were then eaten by the snakes.

Interestingly, juvenile Spiny Chuckwallas seem to make up a large proportion of the diet of dwarfed Speckled Rattlesnakes on islands in Los Angeles Bay (Table 1). Three of six *C. mitchellii* specimens collected from Cabeza de Caballo Island contained chuckwalla remains, as did one of three specimens collected from Smith Island. Case (1978, 2002) suggested that Speckled Rattlesnakes from Ángel de la Guarda Island attained large size in response to their chuckwalla prey, and Meik et al. (2010) found some evidence to support that hypothesis. If so, then why have rattlesnakes on smaller islands in Los Angeles Bay, which also eat *S. hispidus*, decreased in body size? One possibility is that selection for small body size on small islands may counter and supersede selection for exploiting the largest available prey, and hence increased body size, on these islands (see Palkovacs 2003). Alternatively, populations of dwarfed rattlesnakes on islands in Los Angeles Bay might have only recently been exposed to colonizing populations of Spiny Chuckwallas, and insufficient time might have elapsed for these rattlesnakes to exhibit phenotypic response to the availability of large chuckwalla prey. Molecular evidence indicates that *S. hispidus* evolved *in situ* on the ancient island of Ángel de la Guarda (1.5–2 million years old; Carreño and Helenes 2002), and may have only recently colonized land-bridge islands of Los Angeles Bay (Petren and Case 1997). In contrast, populations of Speckled Rattlesnakes on islands of Los Angeles Bay were likely isolated from mainland populations as sea levels rose in the early Holocene (< 10 thousand years ago; Carreño and Helenes 2002).

Acknowledgments.—This research was partially supported by an Explorer's Club Exploration Fund grant and a T&E Inc. grant to JMM and an IU DGS grant in aid of research to AML. We thank C. Casola, E. Gercke, and C. Muir for field assistance, E. Dugan and E. Taylor for comments on the manuscript, K. Beaman for logistic support, and M. Haecker from the Smithsonian Institution, NMNH, for identification of bird remains. Fieldwork in Baja California was conducted under permits granted by the Mexican government (SEMARNAT) to OFV. All specimens were euthanized and preserved following IACUC protocol (UTA A07.021). We are grateful to C. Ramón Godínez Reyes, I. Fuentes Allen, and O. Candelario López Pinto of the Area de Proteccíon de Flora y Fauna Islas del Golfo de California (CONANP) for logistical and permit assistance. OFV thanks CONACyT, DGAPA-UNAM, and J. Campbell for support during sabbatical at UTA. We also thank E. Perez Ramos and C. Franklin for accessioning specimens.

Distributional Data for *Bolitoglossa* (Amphibia, Caudata, Plethodontidae) from Nicaragua and Costa Rica

The genus *Bolitoglossa* is the largest and most widely distributed group of neotropical lungless salamanders (Parra-Olea et al. 2004). There are 121 species (AmphibiaWeb 2012) of small to large, relatively robust salamanders distributed from northeastern Mexico to southern Amazonian Brazil (Savage 2002; Wake and Lynch 1976). Although most species in the genus occur in Middle America, there are only four species in Nicaragua (the largest and most centrally located country in Central America; Sunyer and Köhler 2010): *B. indio*, *B. insularis*, *B. mombachoensis*, and *B. striatula*. *Bolitoglossa indio* is a species known only from the holotype, collected at 25 m elevation in Dos Bocas de Río Indio, Dept. Río San Juan (Sunyer et al. 2008). The remaining three species, *B. insularis*, *B. mombachoensis*, and *B. striatula*, are presumed closely related (S. M. Rovito, pers. comm.) and allopatric. *Bolitoglossa striatula* is a relatively widespread species with a distributional range from northeastern Honduras to southeastern Costa Rica, primarily on the Atlantic versant, from near sea level to 1052 m elevation (Savage 2002). *Bolitoglossa mombachoensis* and *B. insularis* are species endemic to higher elevations of cloud forest habitat on two forested and isolated volcanoes of the Pacific versant of Nicaragua. *Bolitoglossa mombachoensis* is a locally abundant species (Jansen and Köhler 2001) restricted to higher altitudes (950–1345 m elevation) of Reserva Natural Volcán Mombacho, Dept. Granada (Köhler and McCranie 1999; Köhler 2011); and *B. insularis* is known only from the holotype, collected at 800 m elevation in Reserva Natural Volcán Maderas on Isla de Ometepe in Lago de Nicaragua, Dept. Rivas (Sunyer et al. 2008).

During fieldwork conducted in October and November 2009 in Nicaragua we collected several specimens that extend the known vertical distribution of *Bolitoglossa insularis*, *B. mombachoensis*, and *B. striatula*. All referred specimens were verified by Theodore J. Papenfuss and Sean M. Rovito and are deposited in the Museum of Vertebrate Zoology (MVZ), University of California, USA, and in the Museo Herpetológico de la UNAN-León (MHUL), Universidad Nacional Autónoma de Nicaragua-León, León, Nicaragua. We also report information on a Costa Rican specimen of *B. indio* in the British Museum of Natural History (BMNH), London, UK. Figure 1 depicts collection localities discussed below. Geocoordinates are based on datum WGS84.

Bolitoglossa indio: COSTA RICA: ALAJUELA: Cantón de San Carlos: Boca de Arenal, 68 m elev. First country record. On 20 September 2011, D. B. Wake examined specimen number BMNH 96.10.8.77 (Fig. 2a) collected by C. F. Underwood in 1890. This specimen has had a long history. It was first mentioned (but not illustrated) by Günther (1885–1902) as *Spelerpes variegatus* (a composite of species in which he included specimens now assigned to *Bolitoglossa alberchi*, *B. mexicana*, *B. mulleri*, *B. platydactyla*, and *B. salvinii*) and reported it to have been obtained from "San Carlos, Costa Rica." Dunn (1926) discussed the specimen briefly in an addendum to his monograph on the Plethodontidae. At the time Dunn worked, only 30 species of tropical salamanders were known (today there are 121 species of *Bolitoglossa* alone, AmphibiaWeb 2012); many of them were composites of sometimes unrelated species. Under the heading "*Oedipus platydactylus*" Dunn (1926:440–441) listed six specimens in the British Museum of Natural History that he had examined, one from British Honduras, two from Guatemala, the specimen in question from Costa Rica, and two specimens from Colombia. While Dunn noted that this Costa Rican specimen might represent an undescribed form, he stated forcefully that of then-recognized species it fit only into *O. platydactylus*. None of these six specimens is today considered a member of *Bolitoglossa platydactyla*, and as early as 1952 Taylor questioned the identification of the San Carlos specimen. However, in the absence of additional specimens, Taylor took no formal action. When Taylor (1954) described *B. alvaradoi* and *B. arborescandens* (the latter synonymized with *B. alvaradoi* by Savage 2002), he made no mention of the specimen in question. Wake and Brame (1962) assigned the specimen to *B. alvaradoi*, and Savage (2002) accepted this decision. However, Savage added more exact geographic information "Alajuela: San Carlos: Boca de Arenal." Savage (in litt. to DBW, 22 February 2012) explained his reasoning. Underwood was a well-known ornithologist and general naturalist, and he is known to have traveled with the ornithologist M. A. Carikker, Jr. (Carriker 1910). The locality "San Carlos" may seem vague, because the name in its most general sense refers to the Cantón de San Carlos in the Provincia de Alajuela. The Canton is the largest of the 81 cantons in Costa Rica, and includes territory between the Cordillera Central and the Nicaraguan border, with the San Carlos River a central feature. Savage (1974) considers Underwood's "San Carlos" to refer to the village known today as Boca de Arenal, following Carriker's (1910) statement that the

name as used by collectors refers to the head of navigation up the Río San Carlos (above the Río San Juan) and the beginning of the old land route to the Meseta Central. The site, then known as the Comandancia de San Carlos, is today's Boca de Arenal (see Fig. 1). If we accept this reasoning, the assignment of this specimen to *B. indio* extends the known geographical range of the species approximately 87 km to the southwest from the type locality (see Fig. 1), along the San Carlos River south of the San Juan River. Therefore, this species is no longer considered a Nicaraguan endemic.

BMNH 96.10.8.77 is an adult male that has the following dimensions (in mm): Standard length (SL, snout to posterior end of vent) 46.8, tail approximately 42, head width 7.3, forelimb length 10.7, hind limb length 12.9, width of pes 4.9. There are 3 premaxillary teeth and 68 maxillary teeth. The vomerine teeth were not countable, but were in a long, strongly curved row. The foot is especially broad and the fifth digit of the pes is large and stout. Although rather desiccated, color preservation is good. The moderately dark ground color of the dorsal surfaces is covered with extensive light patches that appear to lie superficially above the ground color. These patches are sharply demarcated from the ground color. Light pigmentation is marked on the back of the head and over the shoulders. Small, isolated spots of pigment are found in the mid-dorsal region, where they form two vaguely defined rows that coalesce over the pelvic region. Only 5–6 spots are clearly isolated, with the others partly joined. Spotting is extensive on the tail, with the spots usually slightly to extensively connected. Assignment to *B. indio* is based on close similarity in morphology (see below) and in color pattern (see Fig. 2a), therefore BMNH 96.10.8.77 constitutes the second published record of this species (Sunyer et al. 2008). Because of the rarity of the species, we present here detailed comparisons of the specimens. They are both exactly the same size (46.8 SL), but the holotype is female. The holotype has a slightly broader head and a substantially shorter tail (34.8), but the posterior 40% of the tail of the holotype appears to be regenerated, accounting at least in part for its shorter length. The pes is about the same width (5.1 in holotype) and the hind limbs about the same length (10.9). There are substantially more maxillary teeth in the Costa Rican specimen than in the holotype (68 vs. 48). On the whole the two specimens are similar and measurement differences may relate at least in part to preservation artifacts.

Some further comments on *Bolitoglossa indio* are in order. It is possible that a population of salamanders at Rara Avis (see Fig. 2b), adjacent to and upslope from the La Selva Biological Station, Costa Rica, is attributable to *B. indio* (compare Fig. 2b with Fig. 1b in Sunyer et al. 2008). If this is the case, there are several implications. First, the elevational record for this species would extend upwards to 710 m elev. Second, the species is misassigned to the subgenus *Bolitoglossa* and instead is a member of the subgenus *Pachymandra*, based on the fact that a specimen from Rara Avis was used by Parra-Olea et al. (2004) as their representative of *B. alvaradoi*. An x-ray of the holotype of *B. indio* indicates that the transverse processes of the first caudal vertebrae are not branched, as are those of other members of *Pachymandra* (*B. alvaradoi* and *B. dofleini*). These processes arise at the very anterior end of the vertebra, are very long, and overlap the processes on the last caudosacral vertebra. This qualifies as a "complex" tail base, characteristic of *Bolitoglossa* beta of Wake and Lynch (1976), which characterizes the subgenera *Magnadigita*, *Nanotriton*, *Mayamandra*, *Oaxakia*, and *Pachymandra*. We have x-rayed BMNH 96.10.8.77 and it too, has a complex tail base, although differing from the holotype of *B. indio* in having a bifurcated transverse process of the first caudal vertebra. While this is the usual beta pattern, absence of the bifurcation is also found occasionally in specimens of other species belonging to the above subgenera, and what is most important is the crossing of the transverse processes of the adjacent last caudosacral and first caudal vertebrae. We do not know the condition of the vertebrae in the Rara Avis population, but specimens assigned to *B. alvaradoi* have invariably had the complex tail base, with bifurcated transverse processes on the first caudal vertebra. In addition, some specimens of *B. alvaradoi* from Rara Avis showed a striking change in coloration between day and night time (Twan Leenders, pers. comm.). In contrast, the holotype of *B. indio* was kept living for several days and showed no significant change in coloration. Resolving the question of relationships between *B. indio* and what we now consider its likely closest relative *B. alvaradoi* will require additional specimens and research.

Bolitoglossa insularis: NICARAGUA: RIVAS: Reserva Natural Volcán Maderas (11.45643°N, 85.50845°W), Isla de Ometepe, 1050 m elev. (see Fig. 1). 13 November 2009. J. Sunyer and L. A. Obando. Adult female (MVZ 264228; Fig. 3). The specimen was found active on a fern's leaf 1.5 m above the ground at night time (2030 h) near a rather windy ridge along the trail from Finca Magdalena to the top of the volcano in pristine Premontane Moist Forest formation (Holdridge 1967). At the time it was found, the coloration of MVZ 264228 was homogeneously immaculate yellowish to brownish dorsally and immaculate white ventrally

FIG. 1. Map of Nicaragua and Costa Rica showing the localities mentioned in text. Water surfaces are colored blue. Areas below 600 m green. Areas above 600 m brown. Areas above 1200 m dark brown.

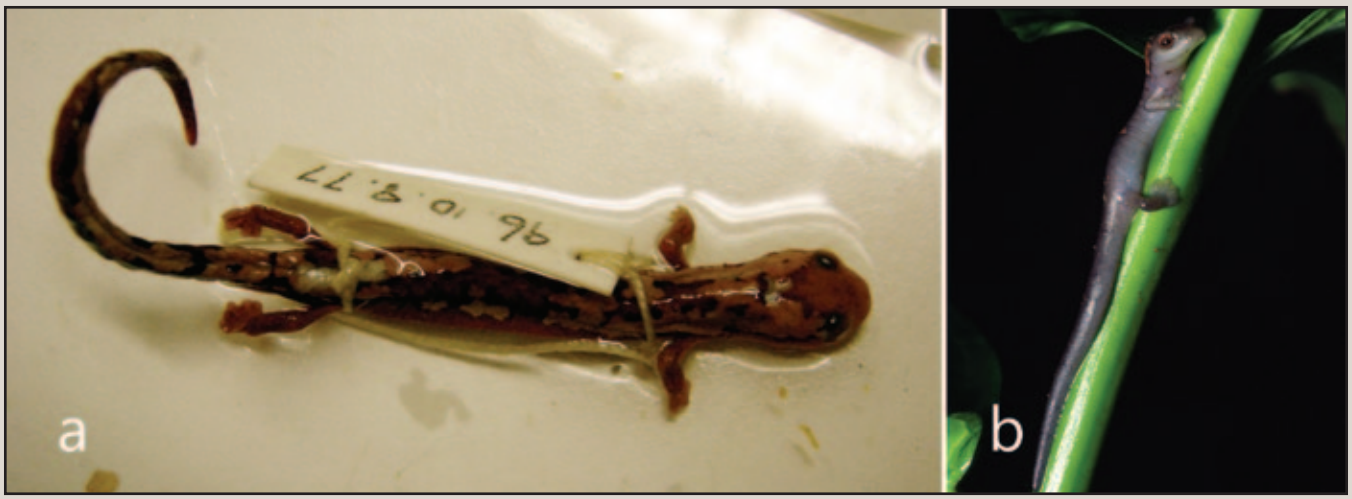

FIG. 2. (a) Preserved adult male *Bolitoglossa indio* (BMNH 96.10.8.77) from Boca de Arenal, Cantón de San Carlos, Provincia de Alajuela, Costa Rica, 68 m elevation (see text), and (b) adult specimen of *B. alvaradoi* from Rara Avis, Provincia de Heredia, Costa Rica, 710 m elevation.

FIG. 3. Adult female *Bolitoglossa insularis* (MVZ 264228) from Reserva Natural Volcán Maderas, Dept. Rivas, Nicaragua, 1050 m elevation. Compare color change between (a) the moment it was found, and (b) after manipulation.

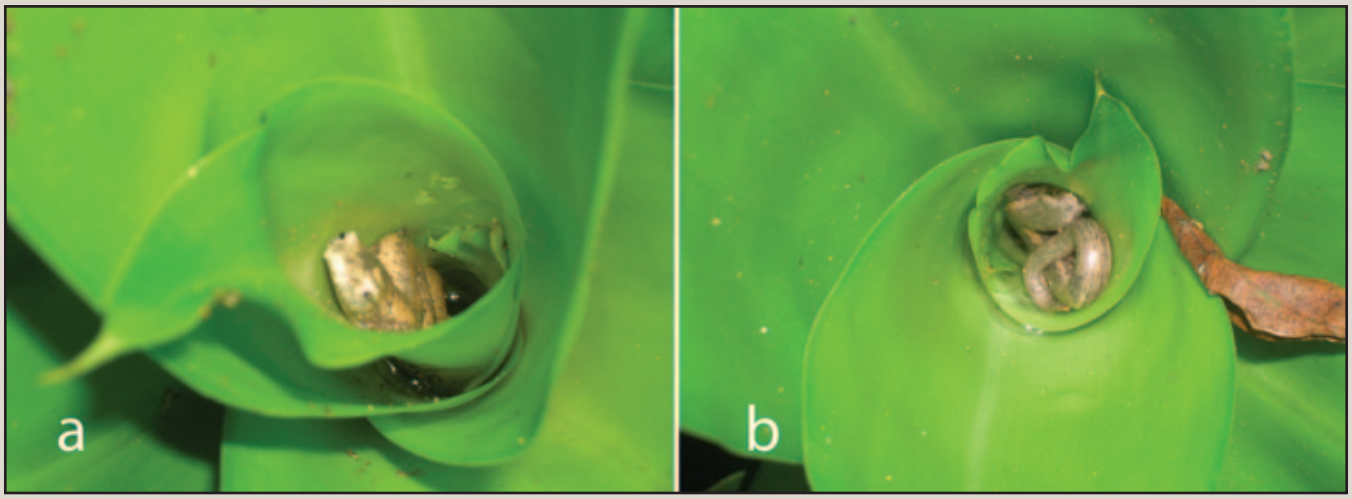

FIG. 4. (a, b) Non-collected adult specimens of *Bolitoglossa mombachoensis* from Reserva Natural Volcán Mombacho, Dept. Granada, Nicaragua, 875–900 m elevation. These and few other specimens were found at day time around the small pond created by rains in the apex of the water-filled tank of the bromeliad-like leaves of *Dracaena fragans*, a plant locally used to delimit coffee plantation parcels.

FIG. 5. Adult female *Bolitoglossa striatula* (MVZ 264227) from Finca Monimbó, Dept. Matagalpa, Nicaragua, 1380 m elevation.

(Fig. 3a). Immediately after manipulation, the specimen quickly developed two pairs (one lateral and one dorsolateral) of non-delimited and weakly defined dark brown shadings (Fig. 3b). Dorsal surfaces of the head and limbs also turned slightly darker, coming to resemble the coloration of the holotype, which differs from MVZ 264228 by having a considerably greater number of small, dark brown spots, giving a mottled appearance to the entire dorsal and ventral surfaces of the head, body, and tail (see Fig. 2 in Sunyer et al. 2008). This color change was not observed in the holotype, which was collected by day; accordingly, we suspect the species presents alternative coloration by night (Fig. 3a) and day, being slightly darker by day as well as under stressful conditions (Fig. 3b). We additionally observed MVZ 264228 using its prehensile tail proficiently as a fifth limb. MVZ 264228 constitutes the second published specimen of *Bolitoglossa insularis* and extends the known altitudinal range of the species by 250 m (Köhler 2011; Sunyer and Köhler 2010; Sunyer et al. 2008), thus with a total elevational range of 800–1050 m. Unconfirmed sight records of local rangers and tourist guides indicate the presence of this species at even higher altitudes, and the species likely occurs all over the upper portions of this 1394 m elevation, humid and forested volcano.

Bolitoglossa mombachoensis: NICARAGUA: GRANADA: Reserva Natural Volcán Mombacho (11.83831°N, 85.99277°W), 875 m elev. (see Fig. 1). 18 November 2009. J. Sunyer and L. A. Obando. Adult female (MHUL 007). The specimen was found during the day in the central-most portion of *Dracaena fragans* (a plant locally used to delimit coffee plantation parcels), 1.5 m above the ground. It was collected along the road from Hacienda El Progreso to the top of the volcano, at exactly the transitional area between the coffee plantation and the reserve's forest, in Premontane Moist Forest formation (Holdridge 1967). While manipulating MHUL 007 we observed it could proficiently use its prehensile tail as a fifth limb. Although the species is, at this premontane elevation, not as abundant as at higher altitudes, several other specimens were observed during the day in the same general area (875–900 m elevation) hidden in the apex of these plants (Fig. 4). This record extends the known altitudinal range of *Bolitoglossa mombachoensis* by 75 m (Köhler 2011), so that the species is currently known to occur from 875–1345 m elevation, roughly the total extent of the core of the protected area on Volcán Mombacho.

Bolitoglossa striatula: NICARAGUA: MATAGALPA: Finca Monimbó (13.03173°N, 85.88682°W), 1380 m elev. (see Fig. 1). 18 October 2009. J. Sunyer and L. A. Obando. Adult female (MVZ 264227; Fig. 5). The specimen was found active at night along a trail inside the coffee plantation property in Lower Montane Moist Forest formation (Holdridge 1967). It was found 0.5 m above the ground on a leaf of a red ornamental introduced plant locally used to delimit coffee plantation parcels, which dominate the area. This record extends the known altitudinal range of *Bolitoglossa striatula* in Nicaragua by 610 m (Sunyer and Köhler 2010; Villa 1972) and in its whole distributional range by 328 m (Köhler 2011; Savage 2002); the species is currently known to occur from about sea level to 1380 m elevation.

Acknowledgments.—All specimens were collected under the regulations of permit No. 006–062009 and exported under regulations of permit No. DGPN/DB-002-2010 provided by the personnel of MARENA (Ministerio del Ambiente y los Recursos Naturales), Managua, Nicaragua. For logistic support, we thank Danilo J. Marenco (Finca Monimbó), José M. Zolotoff and Enoc Pineda (Fundación Cocibolca), Januar López (Guía turístico Mombacho), Gian M. Palazio (Hacienda El Progreso), Salvadora Morales (Fauna y Flora Internacional), and Carlos Flores (Hotel Villa Paraíso). This research was carried out thanks to the "Memorandum of agreement between the UNAN-León and the MVZ" and was entirely funded by the MVZ (Museum of Vertebrate Zoology, University of California, Berkeley, USA). We thank Barry Clarke for help at the Natural History Museum, Jay M. Savage for information and discussion, Josiah H. Townsend and Theodore J. Papenfuss for commenting on the manuscript, and Twan Leenders for field observations and allowing us to use his excellent photograph (Fig. 2b).

Morphometric Analyses and Ontogenetic Variation in a Neotropical Toad (Amphibia, Anura, Cycloramphidae)

The genus *Proceratophrys*, in the family Cycloramphidae (Frost et al. 2006), was first described by Miranda-Ribeiro (1920) and comprises a group of generally similar anuran species (small toads known locally as "horned frogs" or "bullfrogs") that are often confused with species of the genus *Ceratophrys* and *Odontophrynus* (Amaro et al. 2009; Hoogmoed 1990; Izecksohn et al. 1979; Izecksohn and Peixoto 1981). *Proceratophrys* currently comprises 24 species distributed throughout various morphoclimatic regions in South America (Frost 2011; Martins and Giaretta 2011; Napoli et al. 2011) and the species *P. cristiceps* (Fig. 1) studied here is found in the large Brazilian domain of semi-arid intermontane and interplain depressions known as the "Caatinga" (Ab'Saber 1977; Vieira et al. 2008).

Very little information about *Proceratophrys cristiceps* is currently available beyond its original description, although works by Lynch (1971) and Vieira et al. (2007, 2008) focused on the osteology of this species and provided descriptions of its tadpole phase and its morphometric variations.

Ontogenetic studies examining allometric variability in anuran amphibians are not very common, and are practically non-existent for the genus *Proceratophrys*, with publications concerning this taxon being largely restricted to descriptions of their morphology (Giaretta and Sazima 1993; Izecksohn and Peixoto 1980; Martins and Giaretta 2011; Mercadal de Barrio and Barrio 1993; Napoli et al. 2011; Prado and Pombal 2008) or, more rarely, their ecology and natural history (Boquimpani-Freitas et al. 2002; Giaretta et al. 1998; Izecksohn and Peixoto 1996; Sazima 1978).

Allometric studies of different body parts and organs have been used in mathematical models, which have been adapted or modified over time (Bartoletti et al. 1999; Jolicoeur 1963) and have greatly contributed to phylogenetic studies, by facilitating descriptions of these structures and in identifying corresponding body parts and organs that might otherwise have been considered structurally independent and not homologous (Houck 1990; Wiley 1981). Morphological studies generally focus on factors or structures that appear to have a significant importance in the evolution of the structural or functional characteristics of animal, and ontogenetic studies often focus on allometric relationships and their ecological implications (Di Cerbo and Biancardi 2010; Strauss and Altig 1992; Tejedo et al. 2010; Withers and Hillman 2001)—thus extending the scope of descriptive morphology.

As such, the current work contributes to our knowledge of the species *Proceratophrys cristiceps* by analyzing proportionality in this species, describing the differences between the principal ontogenetic categories during the terrestrial phase of this anuran, and discussing the probable ecomorphological significance of the variations encountered. This information should be useful in further studies of the systematics and ecology of this genus, as well as other taxa of Neotropical toads.

Fig. 1. Adult individual of *Proceratophrys cristiceps*.

Methods.—A total of 79 individuals of *Proceratophrys cristiceps* were collected in the Pedra da Boca State Park (6.7716°S, 35.6555°W), in the Municipality of Araruna, in the Curimataú Oriental Valley (Borborema geographical meso-region) in northern Paraíba State, Brazil. Both passive and active techniques were used to capture specimens of *P. cristiceps*. The passive techniques used drift fences with pitfall traps, while active collecting employed standard procedures of searching the leaf litter and manual capturing, following the techniques suggested by Heyer et al. (1994) for amphibians.

The captured specimens were euthanized according to internationally recommended techniques for amphibians and reptiles (HACC 2004); the species were subsequently fixed in 4% formalin, preserved in 65% alcohol, and deposited in the Herpetological Collection of the Department of Systematics and Ecology, Centro de Ciências Exatas e da Natureza at the Universidade Federal da Paraíba (UFPB 08423–8502).

Of the 79 individuals of *Proceratophrys cristiceps* collected, 38% were adults, 34% were subadults, and 28% were young individuals, thus forming an adequate growth series for allometric analyses (Abdala and Giannini 2002). The ontogenetic classification of *P. cristiceps* followed the suggestions of Izecksohn and Peixoto (1980, 1981) and Barrio and Barrio (1993), in which animals with snout–vent lengths (SVL) less than 26 mm were considered young individuals; those having SVL of 26–35 mm were considered subadults; while animals with SVL greater than 35 mm were considered adults.

Traditional allometric analyses of the 79 specimens of *Proceratophrys cristiceps* were performed using nine basic measurements (Fig. 2), expressed in millimeters (mm). Measurements were made using a vernier caliper with a precision of 0.05 mm, according to the methodologies described for morphometric studies by Giaretta and Sazima (1993) and modified by Hayek et al. (2001). The measurements included: snout–vent length (SVL), head width (HW), internarial distance (IND), eye-nostril distance (END), eye length (EL), tibia length (TL), foot length (FL), length of internal metatarsal tubercle (IMT), and the distance from the nostril to the most anterior extremity of the rostrum (DNR). These measurements were chosen for their ecological relevance in ontogenetic studies of anuran amphibians (Blouin and Loeb 1991; Emerson 1978) and are considered by taxonomists to be the most informative measurements for the group (Eterovick and Sazima 1998; Giaretta et al. 2000).

Discriminant analyses using logarithmic values were used (Wiley 1981) to determine if the age classes chosen represented well–defined operational ontogenetic units. Allometric growth models can only be used in this type of analysis if the samples represent elements within consistent progressions and differ only in terms of their absolute size (Houck et al. 1990).

All metric variables were expressed as log10 values, using the allometric function $y = 10^b x^a$ (Hammer et al. 2011). The coefficients were estimated based on the reduced major axis (RMA), thereby minimizing *x* and *y* errors. The standard error was calculated according to Miller and Kahn (1962). Snout–vent length (SVL) was considered to be the standard length (SL) in the present study, where x = SL. This criterion is common in morphometric studies involving allometry (Zelditch et al. 2004).

Allometric coefficients were compared between the ontogenetic categories in the same manner as the total sample – with the latter analysis indicating that the body proportions of *Proceratophrys cristiceps* varied throughout its terrestrial life cycle. A values equal to 1 indicated that the proportions were observed to be constant because of their isometric behavior; values greater than 1 described allometrically positive effects (increases in relation to the standard length); while values less than 1 indicated allometrically negative effects.

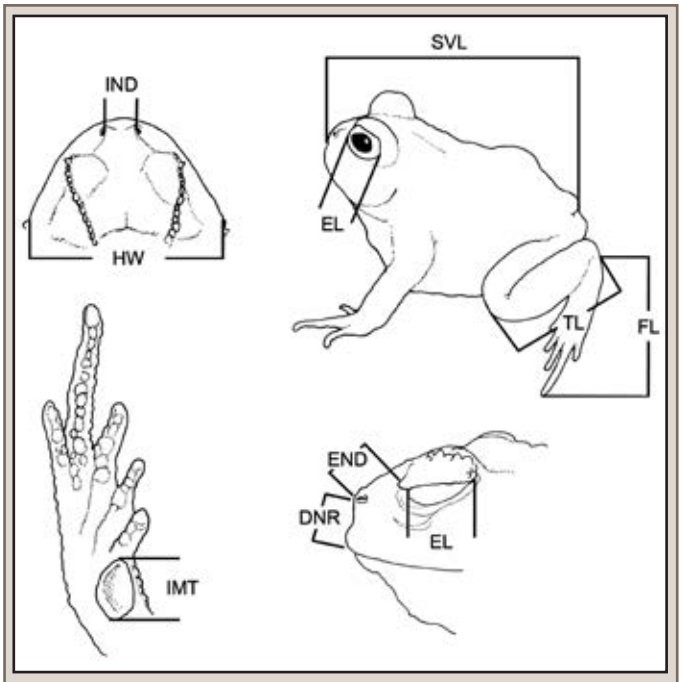

ILLUSTRATION BY KLEBER VIEIRA

FIG. 2. Measures used in studying ontogenetic variation in specimens of *Proceratophrys cristiceps*. Snout-vent length (SVL); head width (HW); internarial distance (IND); eye-nostril distance (END); eye length (EL); tibia length (TL); foot length (FL); length of internal metatarsal tubercle (IMT); and distance from the nostril to the most anterior extremity of the rostra (DNR).

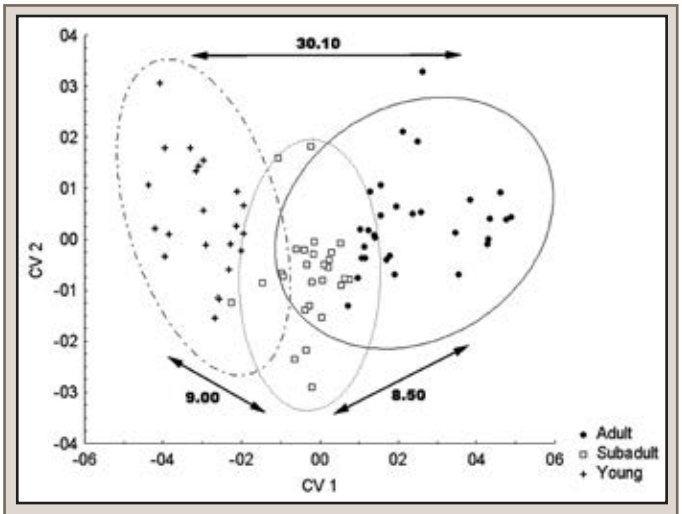

FIG. 3. Discriminant analysis of the ontogenetic categories of *Proceratophrys cristiceps*. The first axis responds for 95% of the observed variance. Arrows indicate the separation of the categories according to their Mahalanobis distances.

Results.—The discriminant analysis function demonstrated that the ontogenetic categories represented well–defined groups along a continuum, with the subadult category being clearly situated in an intermediate position. The results showed that Canonical Variable 1 (CV1) had elevated variance, with the variables SVL and IMT contributing to most to the distinctions

observed between the categories (FIG. 3) and having a consistent size progression; these two variables notably differed in terms of absolute size, indicating that they were reliable variables for allometric studies in this species.

Among the different categories of cephalic proportions examined, significant differences were observed with the traits HW, IND, and END (Table 1). Adults demonstrated typically isometric growth, characterizing a pattern distinct from those of the subadults and the young, as would be expected for this phase of development. The subadult category was different from the others as it demonstrated allometrically positive growth in terms of the internarial distance and the eye–nostril distance; allometrically positive growth in young individuals was only seen in terms of head width.

The three ontogenetic categories demonstrated little variability in terms of measurements related to the hind legs, and no significant divergence from the hypothesis of isometry in subadult and young individuals was noted (Table 1). Only adults demonstrated significant allometrically positive growth in terms of IMT. There was a tendency towards positive allometry in relation to foot development among subadults, although no statistically significant deviation was detected from the isometry hypothesis.

Proceratophrys cristiceps demonstrated relatively isometric growth during its terrestrial life cycle, except in terms of the variables IND, END, EL, and DNR, which demonstrated significantly reduced development in relation to the standard length (SL)—with the three categories demonstrating proportionally larger values when compared individually.

Discussion.—The morphological structures of anurans undergo significant modifications during their development from the tadpole stage to their mature adult terrestrial form, and this group is ecologically quite unique in demonstrating such divergent development (Duellman and Trueb 1994). Almost all anatomical, physiological, and behavioral characteristics are in some manner related to an animal's size and shape (Clutton-Brock and Harvey 1979), making it important to determine the ecological and/or evolutionary forces during ontogenetic variations.

Variation was observed to be significantly allometric in certain parts of the cephalic structure of *Proceratophrys cristiceps* (Table 2), indicating systematic changes in head shape during development (even though certain specific patterns were observed to differ among the different age categories analyzed) (Table 1). These allometric changes almost certainly reflect functional and behavioral changes as this species matures.

Young anuran individuals demonstrated allometrically positive development in terms of both head width and maxillary dimensions that were quite distinct from adults and subadults. This positive development, apparently common in anuran amphibians, suggests a maximization of their adaptation to their natural environment.

Proceratophrys cristiceps demonstrates seasonal behavioral patterns in its natural habitat—which is dominated by two strongly contrasting annual climatic regimes—a rainy season and a marked dry season. These animals excavate underground burrow during the dry season and remain in them until the rains return. Young toads must develop rapidly during the rainy period and store sufficient energy reserves to be able to grow and then survive the long dry period while in their burrows. Wide heads and proportionally large mouths will increase their chances of survival—as researchers have established a direct relationship between the numbers of prey types available and a predator's gape-size (Toft 1981, 1995)—so that allometrically positive head width and maxillary dimension values reflect an important strategy in this phase of anuran developmental.

As their global morphological dimensions become more proportional to one another, these young individuals of *Proceratophrys cristiceps* show reductions of 0.74 mm in their HW for each 1 mm increase in SVL, while subadults show HW decreases 0.4 mm for each 0.45 mm increase in SVL, and adults a HW increase of 0.04 mm for each 0.4 mm increase in SVL—as indicated by a linear equation of the corresponding regression line (data not shown).

While it is known that amphibian development is highly dependent on the regional environment, their growth rates also seem to depend on their ploidy levels. Individuals from seasonal environments marked by annual dry seasons are generally diploids (as seems to be the case for various species of the genus *Proceratophrys*) and they develop rapidly in comparison to animals that are adapted to more humid environments and have polyploid chromosome numbers (Goin et al. 1968).

The IND and END distance indices of subadults were quite elevated and demonstrated positive allometrics (characterizing an elongation of the rostrum) as compared to young individuals and adults. This observation can be understood in terms of the fact that several species of anuran amphibians pass through a phase of skeletal ossification during their post–metamorphic development (Duellman and Trueb 1994) and the alary processes of *Proceratophrys cristiceps* shorten as these animals pass into their adult stage, apparently due to greater ossification. Direct observations of the crania of this species (Vieira et al. 2008) confirmed the presence of wide and long alary processes in young and subadult individuals as compared to adults. The nasals in adults lose their pointed shape at the anterior end, being wide and long nearer the rostrum, contributing to the ontogenetic variations observed in terms of the internarial and eye–nostril distances during the terrestrial phase of this species.

Differences were also observed in terms of the internal metatarsal tubercle (IMT) between the different ontogenetic categories of *Proceratophrys cristiceps*, with the adults demonstrating greater intensity of IMT development—with values differing significantly from the isometric hypothesis. This is not an uncommon occurrence in some anurans, as this structure normally becomes more keratinized as the individuals grow, with young individuals having small and poorly keratinized internal metatarsal tubercles, while this keratinization increases in subadults and reaches a maximum in adults. This is an important trait for this species as this structure is fundamental to its cryptic habits and facilitates burrowing into the soil to hide or to escape from the long dry period (Boquimpani-Freitas et al. 2002; Giaretta and Sazima 1993; Weygoldt and Peixoto 1985)—a behavior trait of adults that appears to begin among subadults.

Young individuals were not observed burrowing into the ground, even when raised in terraria, reinforcing the results seen with the allometric coefficients. Although young toads can be very active (spending a large portion of their time jumping and moving around), both young and subadult animals tend to stay near substrates that can readily camouflage them.

A positive allometric tendency was also observed among subadults in terms of the parameter FL, as they demonstrated increases of 2.4 mm in FL for every 0.5 mm increase in SVL in the linear regression equation; this increase was only 0.13 mm for each 1 mm of SVL among young individuals (data not shown). These values are consistent with the jumping habits of the young and subadults, as long posterior feet are an important feature in jumping ability (Hildebrand 1988). We recorded increases of 0.6 mm in FL to every 0.5 mm increase in SVL among adults, reflecting isometric values. Adults spend most of their time moving very little—depending more on their camouflage to avoid predators and to capture their prey (Sazima 1978), which is consistent with the results observed for this parameter.

As a whole, the terrestrial developmental phase of *Proceratophrys cristiceps* appears to be marked by nonsignificant allometric trends (Table 2), whether positive or negative, that are not significantly different from the isometric hypothesis, especially in terms of body parts not including the head. However, as their standard length increased, IMT, FL, and TL proportionally accompany it—indicating that this species gradually invests in a fossorial habit during its terrestrial development (Table 1)—as demonstrated by the presence of a more cornified IMT, and longer and more robust legs among adults.

There have been relatively few studies of body size and allometry in amphibians, and few researchers have investigated intra- and interspecific variations within this vertebrate group. The present study was introductory, and it is still not possible to determine how much time is needed for young individuals of *Proceratophrys cristiceps* to become subadults and then adults, or fully understand the ecomorphological implications of this transition. Additional comparisons and analyses will therefore be necessary, especially among species that demonstrate similar ecomorphological functions but different phylogenetic histories.

Acknowledgments.—We thank the Instituto Brasileiro do Meio Ambiente e dos Recursos Naturais Renováveis (IBAMA) for authorizing the capture of these animals, and A. Leyva and Roy Funch for helping with the English editing of the manuscript.

Food of Some Lizards from Cumberland Island, Georgia

Cumberland Island is the largest and most southerly barrier island off the coast of Georgia, USA. It is isolated by salt and brackish (estuarine) water. It is about 27 km (17 mi.) long and averages almost 2.4 km (1.5 mi.) wide. There are temporary freshwater ponds dependent on groundwater, which is recharged by precipitation. A rich assortment of habitats is distributed throughout the island and includes maritime forest, freshwater wetlands, beach and interdune, and flatwoods. Despite the occurrence of feral livestock, horses, and swine, the northern portion of the island is designated a Wilderness. There are relatively few small vertebrates present, probably because they are negatively affected by the presence of the feral livestock. Besides trampling, horses consume acorns, Spanish moss, and graze herbaceous understory plants, all food for small mammals and secondarily for reptiles. Besides trampling, hogs root decaying logs and stumps and eat small vertebrates. A mud turtle was once found by CR that had been smashed by trampling. Basic natural history information is required to understand future changes in populations of small vertebrates. Herein we present data on the diet of several species of lizards of Cumberland Island to help understand local population biology as well as to offer comparison between Cumberland Island populations and populations that have been studied elsewhere.

A total of 63 lizards from Cumberland Island was opportunistically collected and preserved over the last three decades by CR. All were taken by salvage (found dead on the road, drowned, or otherwise accidentally killed) from throughout the island and in various areas and months. Most were adults but various size and age classes were included. The lizards' stomachs were removed and sent to JOW. The contents were removed from the stomachs and placed in ethanol in Petri dishes, identified using a 10–70× zoom microscope (Olympus America SZH, Melville, New York), and the percent volume of each item from each stomach was estimated by visual observation (Whitaker et al. 2009). Visual observation was used because there were too many small pieces to bring them together to measure by water displacement. Data were summarized (Table 1) and total percentage volumes ([sum of individual volumes of food]/[total volume of all samples] × 100) were calculated for each food item. Percent frequency ([number of stomachs containing that food]/[total number of stomachs] × 100) was also calculated for each species, indicating the percentage of lizards eating a particular food. We hope that these data will serve as a baseline for further studies of the lizard community in this protected area.

Aspidoscelis sexlineata (Six-lined Racerunner).—The major foods of this species in our sample were spiders, caterpillars, crickets, and cercopids, those items totaling 75.9% by percent volume (N = 24, Table 1). Grasshoppers and crickets, leafhoppers and planthoppers, and spiders are consistently reported as the major foods of this species (Ballinger et al. 1990; Burt 1928; Force 1925; Hamilton and Pollack 1961; Hardy 1962; Hartman 1906; Paulissen 1987; Paulissen et al. 1997; Punzo 1990; Taylor et al. 2011). Adults and larvae of beetles and lepidopterans are frequently reported as well, and various authors (Burt 1928; Hardy 1962; Taylor et al. 2011) have reported land snails as a minor part of the diet of Six-lined Racerunners. In our sample caterpillars were eaten by 42% of individuals and formed 19% of the volume, but mollusks did not appear in our samples. A small amount of plant material (most bits of leaves) was found, probably taken incidentally. The diet of this species on Cumberland Island closely resembled that as reported in the literature except that caterpillars were perhaps more important, and few grasshoppers appeared in our sample.

Anolis carolinensis (Green Anole).—The main food items of the Green Anole in our sample (N = 11, 82.4% volume) were caterpillars, crickets, flies, chrysomelid and carabid beetles, true bugs, spiders, and ants (Table 1). Most anoles (*Anolis* spp.) are primarily insectivorous, but will also feed on plant matter, including leaves, fruit, and nectar (Bartlett 1995; Lazell 1972). While there are many studies of *A. carolinensis* in captivity, little is known of its diet in the wild. Individuals have been observed feeding on nectar and pollen (Himes 1998a; Liner 1996; McCoid 1994), sometimes in conjunction with foraging for arthropods (Campbell and Bleazy 2000). They have also been observed feeding on scorpions, lizards, and possibly bald-faced hornets (Buttenhoff and Hopkins 1996; Himes 1998b; Hughes and Parmalee 1993). Hamilton and Pollack (1961) reported flies, beetles, wasps, and caterpillars in stomachs of six individuals from Fort Benning, Georgia. No plant material was found in our study. Results were similar to those of the other Georgia study (Hamilton and Pollack 1961) except that we found no wasps, whereas they found no crickets, true bugs, or spiders. However, in both Georgia studies, samples were small and the diet appeared to be rather diverse. More study is needed on this species in the wild.

Sceloporus undulatus (Eastern Fence Lizard).—The food most commonly eaten by the Eastern Fence Lizard on Cumberland Island (N = 5, Table 1) was ants (Formicidae, 41% volume, 100% frequency), followed by caterpillars, true bugs, and spiders. These items totaled 87.0% of the food. Elsewhere the Eastern Fence Lizard usually feeds heavily on ants, but other small prey such as grasshoppers, beetles, various larvae, and spiders are often eaten as well (Burt 1928; Force 1925; Hamilton and Pollack 1961; Hartman 1906; McCauley 1939). Carr (1940) stated that beetles and their larvae were the major foods of Florida individuals, but noted that snails were found in a few. The food of this species on Cumberland Island was similar to that elsewhere.

Plestiodon inexpectatus (Southeastern Five-lined Skink).—The sample from Cumberland Island consisted of only two individuals (Table 1), one of which had eaten a wasp, apparently the first record for this species. The other had eaten spiders. Orthopterans and beetles accounted for approximately half of the diet by volume of 24 individuals from Fort Benning, Georgia (Hamilton and Pollack 1961). Rundquist and Collins (1974) found the

most frequent foods of 12 individuals from Kentucky to be spiders, crickets, and cockroaches. Our sample is too small to make any comparisons.

Plestiodon laticeps (Broad-headed Skink).—The foods accounting for the greatest volume in our sample (N = 4, Table 1) were spiders, elaterid and chrysomelid beetles, and caterpillars, comprising 84.3% of the diet. Orthopterans are apparently the major food of this species elsewhere, although many other arthropods, including beetles, lepidopterans, various larvae, isopods, and spiders, are also eaten, and vertebrates occasionally occur in the diet (Franklin 1999; Hamilton and Pollack 1961; Vitt and Cooper 1986). There are reports of this species feeding on fruit (Patton and Messinger 2002; Sorrell et al. 2006; Vitt and Cooper 1986), but it is evidently not a major component of the diet. On Kiawah Island, South Carolina, the prey of 64 individuals consisted mainly of species found in leaf litter or under surface objects (Vitt and Cooper 1986). Because of our small sample size, comparisons to other studies would not be particularly meaningful. CR observed a Broad-headed Skink catch and consume a carpenter bee, *Xylocopa* sp., apparently the first report of this food for this species.

Scincella lateralis (Little Brown Skink).—On Cumberland Island, the most important foods by percent volume from this species (N = 5, Table 1) were spiders, crickets, and caterpillars, totaling 70% of the diet by volume. This species is most often reported to feed on beetles, various larvae, and spiders, though a wide variety of other prey, including millipedes, amphipods, snails, and occasionally vertebrates, are also eaten (Brooks 1963; Burt 1928; Hamilton and Pollack 1961; Lewis 1951; McCauley 1939). Spiders, found in all the Cumberland Island stomachs, were also found in high frequencies in other studies of this skink (Brooks 1963; Hamilton and Pollack 1961; Lewis 1951, Slater 1949). Few beetles were found in our sample, but it was small and otherwise our sample was similar to those elsewhere.

Ophisaurus ventralis (Eastern Glass Lizard).—The most important foods of 12 Eastern Glass Lizards from Cumberland Island by both volume and frequency (Table 1) were crickets and grasshoppers, caterpillars, and spiders, totaling 84.9% of the volume. Hamilton and Pollack (1961) examined the stomach contents of 162 individuals of this species from Georgia and Alabama, most taken in July and August. Caterpillars accounted for nearly half the volume, with most of the rest being isopods, orthopterans, and beetles. Lizards and snakes were occasionally eaten. Orthopterans and spiders formed a higher proportion of the food in our sample, caterpillars a lower proportion.

The main food items of the lizards we examined from Cumberland Island were mostly similar to foods eaten by those species elsewhere. Main items of most were spiders, crickets, and caterpillars, although some species fed secondarily on true bugs and/or beetles, and Eastern Fence Lizards fed heavily on ants (41% volume, 100% frequency). Lizards feed based on availability, yet there is specialization to some degree, as illustrated by the utilization of ants by the Eastern Fence Lizard. Such differences may relate to differences in habitat, to different adaptations, or preferences of the lizards.

Radio-Transmitter Attachment Method for a Small Burrowing Lizard

Research using radio telemetry is central to our understanding of animal behavior under natural field conditions, and is a valuable method for accruing important ecological information such as estimates of home range size, habitat use, habitat fidelity, and dispersal distance for all types of wildlife (Naef-Daenzer et al. 2005; White and Garrott 1990). Information collected can also provide direction when designing and implementing wildlife management strategies or investigating hypothesis driven research questions (Knapp and Abarca 2009). An overwhelming proportion of animal species are small (<20 g), and with reduction in mass and volume of transmitters, telemetry applications can be expanded to new taxa whose spatial behavior and population dynamics are largely unknown, such as arthropods, amphibians, reptiles and fish (Naef-Daenzer et al. 2005). One of the major limitations in radio telemetry is developing a reliable and safe attachment technique since radio-transmitters can affect mobility, increase visibility, or reduce the ability to perform certain behaviors (Blomquest and Hunter, Jr. 2007). An assortment of transmitter attachment methods are available for use on squamates and non-squamates (Hagen et al. 2011; Richmond 1998; Ussher 1999; Warner et al. 2006; Wikelski et al. 2006), and as telemetry becomes increasingly popular, new approaches are being introduced (Brewer et al. 2011; Knapp and Owens 2005; Logue 2007).

Aspidoscelis sexlineata, the Six-lined Racerunner, is a small burrowing lizard in the family Teiidae that is common and widely distributed throughout much of the United States (Conant and Collins 1998; Trauth and McAllister 1996) with the exception of Michigan where it only occurs in one location (Harding 1997; Harding and Holman 1990). Field work to monitor this population since May 2005 indicates low recruitment from juvenile to adult age/size class suggesting that the population may be at carrying capacity. *Aspidoscelis sexlineata* occupies a south-facing hillside located adjacent to a busy road. The lizards prefer bare, sparse, or thick vegetation over forested areas making habitat loss due to natural succession a cause for concern. Even normal roadside maintenance (e.g., mowing, pesticide application) could be a threat to such a small localized population. Recently elevated to Threatened Species Status (Michigan DNR 2009) in the state, data on daily and seasonal movements, habitat use, and home range size for individuals of this isolated population are critical to the development of a science-based management plan for this species in Michigan. Using radio telemetry on such a diminutive creature (mean mass = 5.3 g ± 0.3 g S.E., N = 23; Yoder 2007) presents a variety of challenges including locating individuals, soil interference with transmitter signal, loss of transmitter and animal injury or impairment. Our study is the first to use radio-transmitters on a lizard of this size and habit.

We initiated our radio-telemetry studies in June 2009 on *A. sexlineata* by following the method of Knapp and Owens (2005), who successfully attached transmitters to hatchling iguanas on Andros Island, Bahamas. This method uses monofilament (fishing) line to secure the transmitter anterior to the hind legs of the lizard. We did not try using Tygon tubing as suggested by Knapp and Owens (2005) because we deemed it would be cumbersome to the lizards given their small size. Transmitters used to track *A. sexlineata* were model A2414 (12 mm × 3 mm × 5 mm) from Advanced Telemetry Systems (ATS; Isanti, Minnesota, USA) with a mass of 0.3 g and average battery life of 3 weeks. Transmitters were encapsulated in a waterproof epoxy. They had an attachment tab containing a 1-mm hole on the anterior end and a 10.2 cm long AS-633 super light, flexible stainless steel wire antenna on the posterior end. Only lizards with a mass greater than 3.5 g were selected for transmitter attachment. All transmitters were attached in the field. Lizards were tracked on a south-facing hillside using a hand-held 3-element Yagi directional antenna and R410 Scanning Receiver from ATS. At the end of tracking, efforts were made to locate lizards before they emerged from their burrows, and if located, lizards were dug up to remove transmitters. Of the first six lizards to which transmitters were attached, one was never recaptured. A second lizard experienced significant skin abrasion from the monofilament line and a third suffered a severe laceration on a hind leg. The fourth lizard died when the monofilament slipped over both hind legs and rendered the animal immobile when the antenna became tangled in an underground root system. A fifth lizard escaped the transmitter with monofilament line intact. The sixth lizard was found dead

on the surface with cause of death unknown. Of the two lizards recaptured for transmitter removal both lost mass, 0.2 g and 1.0 g. All recovered transmitters had lost antennae.

As a result of these negative effects, we modified the technique to be less harmful. During the remainder of the 2009 field season and in 2010, we substituted 0.5 mm diameter Stretch Magic bead and jewelry cord for the monofilament fishing line to attach transmitters. The transmitters were placed on the lizard's dorsal surface of the pelvic girdle, and secured with the bead cord wrapped snuggly around the lizard's body anterior to the hind legs and finished with a square knot. A drop of Gorilla Super Glue was placed on the knot to prevent it from slipping, and extra bead cord was trimmed after the glue dried (Fig. 1). On the bottom of the transmitter, a drop of glue was also placed to help hold it in place on the animal's dorsal surface. However, we discovered that this only triggered a shedding response and was not effective; therefore, this step was abandoned for all subsequent attachments. Transmitter antennae were trimmed to 1.3 cm.

Using the modified technique, *A. sexlineata* tracking was conducted from 29 June to 3 September 2009 and 25 June to 15 September 2010 at Murphy Lake State Game Area in Tuscola Co., Michigan. Drift fences and pit-fall traps were used to capture lizards in habitat composed of mostly sandy soils with sparse to thick grassy vegetation and various trees scattered throughout. During the 2009 field season, 11 lizards were fitted with transmitters via the modified method and another 14 lizards were fitted in 2010. Lizards ranged from 3.6–9.9 g in body mass (mean = 6.1 ± 0.2 g) and 51.1–71.5 mm in snout–vent length (mean = 59.3 ± 0.8 mm). Knapp and Abarca (2009) suggest a general rule that transmitter to body mass ratio for lizard species should not exceed 7.5%. Transmitter mass in this study represented 3–8% (mean = 5 ± 0.2%) of an individual's body mass. All transmitters were under 7% of the lizard's body mass, except for one, which was 8%.

Of the 25 lizards fitted with transmitters after modification, one lizard died, and two lizards slipped the transmitter attachment, leaving 22 lizards, which we were able to successfully track. Of these 22 lizards, 14 were recaptured for transmitter removal; our inability to recover the remaining lizards was mostly due to early battery failure. Before attachment, mean mass was 5.9 ± 0.3 g (N = 22). Most recaptured lizards increased mass (mean = +0.43 ± 0.08 g; N = 11); one stayed at pre-attachment mass and two lost mass (mean = –0.15 ± 0.05 g). None of these lizards were gravid. One lizard recaptured in 2010 was fitted with a transmitter from the previous year. This transmitter was attached for 340 days and was easily removed with only superficial skin abrasion. All other outfitted lizards recaptured had transmitters attached for a range of 12 to 21 days (mean = 16 ± 0.4 days). Transmitters were easily removed and also produced only superficial skin abrasions. After transmitter attachment mean mass was 6.4 ± 0.3 g, with a sample size of 14.

Radio telemetry studies require the assumption that an animal's movements and behaviors are not affected by the researchers' methods or techniques (White and Garrott 1990). Our modified method for attachment appears to have no significant effects on the racerunners abilities to run, climb or capture and eat prey. Lizards with transmitters were tracked every two hours for 12 to 21 days. Lizards with transmitters were observed foraging, climbing and running in the same fashion as lizards without transmitters. In June 2010, a lizard without a transmitter was observed eating a Green Danner Dragonfly and in August 2010, an individual with a transmitter was observed eating a large cicada.

FIG. 1. Radio transmitter A2414 from Advanced Telemetry Systems attached to *Aspidoscelis sexlineata* using the modified attachment method.

One downfall to this method is that there is no breakaway mechanism that would allow transmitters to break off as the lizard grows. However, we feel that since natural longevity for most individuals is only 2–3 years (Fitch 1958), the issue of transmitters constraining growth should not be an issue. There is little material needed for this attachment method, making it a quick and convenient procedure, only taking a few minutes to complete in the field. This attachment method has allowed us to reveal previously unknown aspects (e.g., dispersal movements, daily activity movements, burrowing locations, and home range size) of this lizard's behavior and ecology in one of its most northern populations. One particularly interesting discovery was the observation of a dispersal event. We witnessed a lizard move 310.4 m from an area of known habitat to private property previously not known to be occupied by lizards, doubling the known area occupied by lizards. This method should be applicable to other animals of similar size and habit.

Acknowledgments.—We thank Courtney Johnston (2009) and Kelly Dilg (2010) for helping collect data during the respective field seasons and Heather Dawson for review of this manuscript. Funding was provided by a Research and Creative Activity Grant to Szuch and Yoder (2009) from the University of Michigan - Flint Office of Research and from the University of Michigan - Flint Biology Department (2010). The University of Michigan - Flint Office of Graduate Studies provided a Graduate Student Research Assistantship for Larry Buffey, Jr. (2010). We thank Larry Atherton, Director of Laboratories at the University of Michigan - Flint Biology Department, for assistance in acquiring equipment and supplies. This study complied with all applicable state of Michigan land use and scientific collection permits including Endangered Species Permit #1870 issued by the Michigan DNR and was conducted under Animal Use Protocol #09463 issued by the University Committee on the Use and Care of Animals of the University of Michigan.

What the World Needs Is a Better Gopher Tortoise Trap

It is often necessary to capture Gopher Tortoises (*Gopherus polyphemus*) for research or to relocate them from sites slated for development. Tortoises may be captured by hand (McRae et al. 1981), snares, or pulling hooks (Diemer 1992), but most researchers set pitfall (bucket) traps (Breininger et al. 1991; Diemer 1992; Diemer Berish et al. 2000; Landers et al. 1980; McRae et al. 1981; Seigel et al. 2003; Tuberville et al. 2005) or wire live traps (Aresco and Guyer 1999; Brown et al. 1999; Boglioli et al. 2003; Diaz-Figueroa 2005; Eubanks et al. 2003). Many of these capture techniques are labor intensive and their effectiveness depends upon such variables as habitat, burrow location and conformation, season, weather, and trapping expertise.

Pitfall traps consist of 19-L plastic buckets buried at the mouth of adult *G. polyphemus* burrows, with smaller buckets or cans for subadult or juvenile tortoises. Commercially available wire live traps manufactured by Tomahawk™ or Havahart® have one or two doors and a treadle mechanism on the floor that closes the door(s) when triggered by an animal entering the trap.

These traps are set facing the entrance to a tortoise burrow and the treadle mechanism is usually camouflaged with loose sand. The minimum trap size recommended for an adult tortoise is 25 x 61 cm and at least two sizes are needed to trap all size classes typically present in a group of *G. polyphemus* (Ashton and Ashton 2008). Ashton and Ashton (2008) claimed that pitfall and wire live traps were equally efficient at catching tortoises.

Wildlife technicians at Blackwater Wildlife Management Area (WMA) in Florida designed and constructed a new type of wire live trap (flap trap) that they hoped would be easier to install, safer for tortoises, and less disruptive of the burrow microenvironment than pitfall traps. We tested the effectiveness of the flap trap at catching tortoises, compared its trapping efficiency with that of pitfall traps at the same study site, and assessed the relative merits of flap traps, pitfall traps, and wire live traps.

Materials and Methods.—The flap trap sits atop the tortoise burrow entrance and has a one-way trap (flap) door on its floor that a tortoise pushes up when it exits the burrow and that falls shut behind the tortoise once it has fully entered the trap (Fig. 1). The flap door is hinged at the end of the trap closest to the burrow mouth. As the flap opens when a tortoise enters, contact with the top of the trap ensures that the flap will not flip backward and remain open (Fig. 2). In order to achieve a seamless transition between the burrow runway and the edge of the flap-door opening farthest from the hinge, loose sand can be dropped through the top of the trap to ensure that the edge of the flap-door opening is flush with the soil surface. It may be necessary to manually flatten a portion of the burrow apron (mound) to ensure proper positioning. The crawl space must be high enough for a tortoise to exit its burrow without pushing up the body of the trap before encountering the flap door, so adjustments to the position of the trap may be necessary. A tent stake placed on each side of the trap near the hinge of the flap door (Fig. 1) can prevent a tortoise from displacing the trap but may not be necessary for smaller

burrows. Traps may not sufficiently occlude burrow entrances that are large, eroded, or angled; if a tortoise could exit its burrow without entering the trap, soil or logs may be used to block these spaces.

The dimensions of these flap traps are 91 × 61 × 28 cm and the traps are constructed of 14-gauge, 2.54- × 2.54-cm welded cage wire (rabbit wire). A 3.8-m length of 61-cm-wide wire will make one trap (Fig. 3). Besides welded cage wire, materials required for making flap traps are wire cutters or fencing pliers for cutting the wire and ca. 70 J-clips and J-clip pliers for assembling the trap. A 30.5-m roll of wire cost us US$87–134 depending upon the supplier, and one roll made eight traps; each trap cost ca. US$15 in materials. Instead of separately cutting out pieces for the top, bottom, front, and back of the trap, a long piece can be folded to create these pieces (Fig. 3), and only the top and front or back of the trap need to be clipped together, saving construction time and requiring ca. 30% fewer J-clips.

We conducted preliminary tests on the effectiveness of flap traps in the Florida panhandle at Joe Budd Wildlife Management Area (WMA), Blackwater WMA, Pine Log WMA, and Eglin Air Force Base (AFB) in August–September 2008. We checked traps twice daily at 1100–1200 h and 1700–1800 h EDT. The habitat at the latter three sites was sandhill, but at Joe Budd WMA, we trapped in a pasture and along road edges and in clearings in a mixed pine-hardwood forest. If a trap lacked canopy cover, we cut Saw Palmetto (*Serenoa repens*) fronds and laid them over the top of the trap for shade.

We tested the relative effectiveness of pitfall traps vs. flap traps from 13 May through 14 June 2009 in a recently thinned and burned Slash Pine (*Pinus elliottii*) plantation in mesic flatwoods habitat at the Plum Creek/Lochloosa (PCL) site in Alachua County, Florida (Diemer Berish et al. 2012). We did not test wire live traps vs. flap traps. On 13 May, an 8-person team set 63 pitfall and 13 flap traps at potentially occupied burrows, including any with recent tortoise sign. From the potentially occupied burrows identified, we randomly selected 13 burrows for flap traps. We set traps in the morning when tortoises should still have been in their burrows and checked traps each morning. Additional traps of both types were deployed when burrows previously classified as abandoned showed evidence of tortoise use or when new burrows were found. Pitfall traps were 19-L or 11-L white buckets or 4-L black planting containers (depending upon the size of the burrow opening) with holes drilled in the bottom. These traps were sunk directly in front of burrow openings, covered with aluminum foil or newspaper, and camouflaged with loose sand. We shaded pitfall traps with tent-like covers constructed of aluminum (white ceiling soffit) to prevent trapped *G. polyphemus* from overheating. We shaded flap traps with aluminum foil-backed foam sheathing boards (reflective side up) laid on top of the half of the trap closest to the burrow entrance. We cut 61- × 46-cm shade covers from 1.2- × 2.4-m foam sheets and typically attached them to traps using plastic cable ties fed through holes punched in two diagonally opposite corners of the foam sheet. If loose sand or a heavy object is placed atop shade covers to hold them in place, traps may not have to be staked to prevent displacement by tortoises.

To compare the probabilities of capturing a tortoise by pitfall traps vs. flap traps, we performed nonparametric time-to-event analysis using the R statistical environment (R Development Core Team 2009) with the Survival package (Therneau and Lumley 2009). We computed Kaplan-Meier product-limit estimators (Harrell 2001) of the cumulative probability that a trap will have

successfully captured a targeted tortoise emerging from its burrow a specified number of days after being set, while taking into account that, because of flooding or termination of the trapping period, some traps were removed before they had captured a tortoise. Removing a trap corresponded to right censoring the time that passed before it had captured a tortoise. We employed the surv and survfit functions from the Survival package to estimate the functions describing capture probability, and we used the survdiff function to compare the estimators for pitfall and flap traps by log-rank test.

Results and Discussion.—During our preliminary tests of flap traps in the panhandle, in two days of trapping, we captured two tortoises in 13 traps at Blackwater WMA, six tortoises in 16 traps at Eglin AFB, six tortoises in 11 traps at Joe Budd WMA, and nine tortoises in 15 traps at Pine Log WMA. During our comparison of flap and pitfall traps at the PCL site, most tortoises (64%) were captured in the first five days of trapping in May, with both trap types successfully capturing tortoises. Thereafter, captures tapered off. No tortoise was trapped in flap

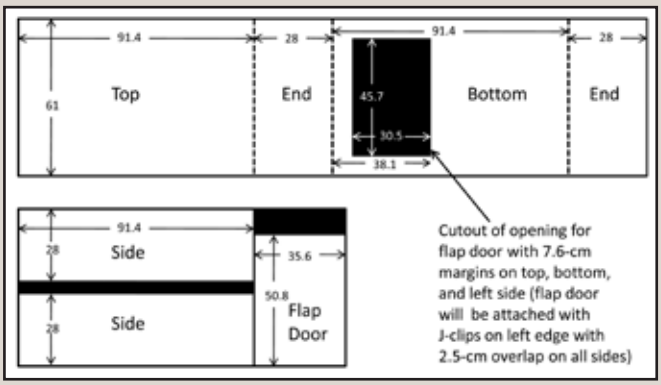

Fig. 3. Schematics of pieces needed to construct one flap trap from 14-gauge 2.54- × 2.54-cm welded cage wire (measurements are in cm and dashed lines indicate sections that can be folded instead of cut out).

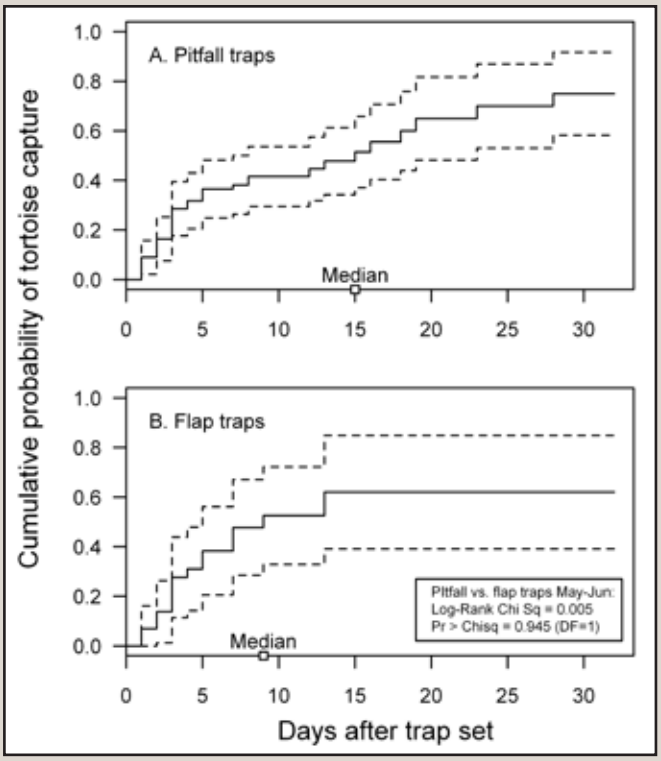

Fig. 4. Comparison of estimated cumulative *Gopherus polyphemus* capture probability between pitfall traps (above) and flap traps (below) during May–June 2009 on the Plum Creek/Lochloosa study site, Florida. Estimated median number of days until tortoise capture is indicated on the abscissa of each plot and 95% confidence limits are dashed.

traps after the first 13 days, whereas six tortoises were trapped in pitfall traps 15–28 days later (Fig. 4). Tortoises trapped in pitfall traps might have been entering burrows instead of exiting them. Capture rates for all tortoises in traps set on the primary trap placement day (13 May) were 68% after 7 days and 78% after 14 days. Capture success of individual tortoises by flap traps during the 13 May–14 June trapping period was 60%, although we never determined whether tortoises were actually present in burrows. When cumulative capture probability of pitfall traps vs. flap traps was compared for 13 May–14 June, the difference was not significant (χ^2 = 0.005, df = 1, P = 0.95; Fig. 4), despite pitfall traps potentially trapping tortoises entering and exiting burrows.

In a previous study in northern Florida involving three sites, including the PCL site, and 11 site-years of trapping, 0.67 tortoises per pitfall trap (excluding recaptures) were captured, and a mean of 76% (range 50–90%) of tortoises was captured within 14 days of traps being set in early or mid-May (Diemer 1992). At two sites during a five-year period, 90–100% of tortoises were captured by the 28th day, but only 64% were captured by the 28th day during one year of trapping at the third site, although 93% had been captured by the 34th day (Diemer 1992). Even in summer, some tortoises may not emerge from their burrows for at least one month (Ashton and Ashton 2008).

Tortoise size did not seem to determine whether a tortoise was captured in flap traps. The smallest tortoise trapped in a flap trap measured 90 mm carapace length. During a later study, we trapped a hatchling tortoise that we suspect entered when the door was pushed up by an adult tortoise that escaped, as evidenced by the presence of adult feces in the trap.

Nontarget species were occasionally trapped in flap traps. We trapped two adult Gopher Frogs (*Lithobates capito*) in flap traps at the PCL site, indicating that they were able to push the door open far enough to enter a trap. We captured two Nine-banded Armadillos (*Dasypus novemcinctus*) together in a flap trap that had been set for three days. We released the armadillos and replaced the trap at the burrow and trapped an adult female tortoise nine days later. We have used flap traps elsewhere to trap nuisance armadillos from their burrows in yards, and this use for flap traps may prove at least as popular as for *G. polyphemus*. A flap trap set at a *G. polyphemus* burrow in Hillsborough County, Florida, captured four juvenile Argentine Giant Tegus (*Tupinambis merianae*) in less than one day, although one tegu was small enough to escape through the wire mesh when approached (B. Kaiser, pers. comm.).

We assessed the relative merits of the three types of tortoise traps by looking at 21 attributes (Table 1). The flap trap had 13 positive attributes, whereas the wire live trap had 12 positive attributes and the pitfall trap nine positive attributes. These attributes are discussed in more detail below. We did not include the important attribute of trapping efficiency because wire live traps were not tested in our study. A study in Georgia using 278 wire live traps indicated that the wire live trap was at least as efficient as the other two types of traps at catching *G. polyphemus*; all tortoises were captured by the 23rd day, with a mean capture time of 4.2 days and a median capture time of three days (C. Guyer, pers. comm.). However, the Georgia study is not directly comparable because all burrows were known to contain tortoises and different environmental conditions may have affected tortoise activity and behavior.

A burrow may contain more than one tortoise and flap traps allow multiple captures at the same time; pitfall and wire live traps rarely catch two tortoises. A pitfall trap can catch tortoises entering or exiting a burrow, whereas wire live traps and flap traps capture only exiting tortoises. Thus, pitfall traps have an advantage when the goal is to catch as many tortoises as possible, but they have a disadvantage when trying to verify burrow occupancy. Tortoises rarely escape from traps of any type, but in our studies, a tortoise avoided entering a flap trap by dislodging it and another tortoise dug under one side of a trap.

The probability of death of trapped tortoises varies among traps. Tortoises trapped in pitfall traps can drown and are probably more susceptible to predation and overheating. We

TABLE 1. Relative merits of three types of *Gopherus polyphemus* traps (wire trap refers to a commercial Tomahawk™-type trap), with ++ indicating a highly positive attribute, + a slightly positive attribute, – a slightly negative attribute, and –– a highly negative attribute.

Attribute	Pitfall Trap	Flap Flap	Wire Trap
Cost	++	–	––
Trap assembly time	+	––	+
Trap installation time	–	+	+
Ease of installation (includes equipment needed)	–	+	+
Ease of transport and storage (assuming noncollapsible traps)	+	–	–
Trap durability (multiple reuse)	–	+	+
Capability of multiple captures without being reset	–	+	–
Amount of stress to captured tortoises	–	+	+
Likelihood of injury	+	–	–
Likelihood of burrow abandonment by trapped tortoise	–	+	+
Probability of death of trapped tortoises by			
drowning	–	+	+
overheating	+	–	–
predation	–	+	+
Potential for trap being tripped by nontarget species	–	+	+
Amount of disturbance to apron and burrow runway	––	+	+
Potential for trap being tripped by rainfall or other abiotic events	–	+	+
Capability of two-way captures (leaving or entering burrow)	+	–	–
Potential for destruction of eggs	–	+	+
Flexibility of installation (% of burrows that cannot be trapped)	+	–	–
Capability of capturing all sizes of tortoises (size bias)	++	+	–
Probability of trap being stolen	+	–	–

experienced no mortality of tortoises in pitfall or flap traps, even in the study in August–September using unshaded flap traps. However, we had to replace flooded pitfall traps with flap traps after heavy rainfall in May at the PCL site to prevent the drowning of tortoises. Heavy rainfall probably affected tortoise emergence and resulted in flooding of 14 burrows at which traps had been deployed. Rainfall also occasionally caused the covers of pitfall traps to collapse under the increased weight of the waterlogged covering sand. (If we had used paper instead of aluminum foil, all the pitfall trap covers would probably have collapsed.)

Tortoises trapped in flap traps occasionally scraped their forelimbs and feet trying to burrow through the wire of the flap traps, but none of these injuries appeared serious enough to require treatment. This type of injury rarely occurs in wire live traps (C. Guyer, pers. comm.). Such injuries could be avoided by using a smaller mesh size of the same gauge for flap traps, but this also might deter some tortoises from exiting their burrows because of greater visibility of the traps. If we had checked our traps more than once a day, stress and injury to tortoises may have been reduced. Although the pattern was not found to be statistically significant, *G. polyphemus* exhibited an increase in the stress hormone corticosterone when left in a Tomahawk™ live trap for up to 12 h, suggesting that trapped tortoises do experience a biologically meaningful capture stress (Ott et al. 2000). Although not tested, one might expect that a large tortoise stuck head-down in a pitfall trap would be more stressed than a tortoise able to move around in a flap trap.

The cost of materials needed to construct one flap trap was ca. US $15. Cutting out and assembling a flap trap took about 1 h. In contrast, a Tomahawk™ or Havahart® 1-door wire live trap measuring 81 × 25 × 30 cm (25 cm is the recommended minimum width for adult tortoises) cost ca. US $60, excluding shipping. Used 19-L buckets for pitfall traps can sometimes be obtained for free, but new buckets usually cost ca. US $4 each. In addition, an electric drill is needed to create drainage holes and a shovel or a post-hole digger is needed to excavate the holes for placement of the buckets. A machete, pruner, and axe are also sometimes needed. Installation of flap traps often requires no tools, but a hand pruner and a shovel or trowel help modify burrow aprons for proper placement of some traps. Installing a 19-L bucket takes approximately four times as long as setting a flap or wire live trap, which typically takes 1.5–4.0 min, including staking down the trap and attaching a shade cover.

The difficulty of installing pitfall traps depends upon soil type and the degree of soil compaction; presence and size of surface or buried roots, stumps, or rocks; presence of shrubs or trees; presence of Red Imported Fire Ants (*Solenopsis invicta*); and other factors. Flap traps cannot be set effectively if a burrow opening is immediately under a large log or stump or at the base of a berm. Burrows with a heavily eroded entrance sometimes cannot be effectively trapped because exiting tortoises can avoid entering the trap. The percentage of burrows at which flap traps cannot be used depends upon habitat type, amount of coarse woody debris, shrub cover, and microtopography. At some sites, we were able to set flap traps at ca. 95% of burrows.

As with other traps, flap traps set in open areas should be shaded to prevent overheating of trapped tortoises. We recommend shading (either with natural or manufactured materials) the portion of the trap closest to the burrow opening, because our preliminary research suggests that a shade cover positioned

there is less alarming to an exiting tortoise, possibly because the cover is not in its line of sight. An additional benefit of a shade cover in this position is that a trapped tortoise will be able to rest in the shade on top of the relatively cool air from its burrow instead of being exposed to radiant heat from its burrow apron. At the PCL site, we often provided additional shading along the sides of the flap trap, which might have affected our trapping success by spooking exiting tortoises. We tended to have better trapping success in our preliminary study, in which most traps were not shaded, but seasonal or geographical differences may have affected success.

Pitfall traps are much easier to transport and take up less storage space than flap and wire live traps. A loop of rope or other material attached to one end or side of a flap trap can serve as a handle to assist in carrying traps in the field. Plastic buckets degrade over time, particularly if exposed to sunlight. Flap and wire live traps are galvanized and will last a long time, although J-clips exposed to the elements will eventually rust and need to be replaced on flap traps. Tomahawk™ makes a collapsible one-door wire live trap that costs ca. US $83 and requires 1/10 as much storage space as a flap trap. A flap trap could be made collapsible for transport and storage by not clipping together the top and sides of the two ends of the trap, which could be assembled in the field using plastic cable ties. A flap trap has 1.8 times the surface area of a wire live trap measuring 58 × 25 × 30 cm; thus, fewer can be transported or stored.

A major drawback of pitfall traps is disturbance to the apron and runway of the burrow. While digging the bucket hole, a clutch of tortoise eggs may be disturbed or damaged. Tortoises nest most frequently in the apron of active burrows, and eggs are present from May through October (Butler and Hull 1996), when tortoises are most active and likely to be trapped. We do not know whether the degree of burrow and apron disturbance affects the likelihood of a tortoise abandoning a burrow; if so, based on our research, flap traps would be less disruptive.

All three types of tortoise traps have advantages and disadvantages. When trapping tortoises during hot, humid Florida summers, we feel that the greater ease of installation and potentially reduced burrow impact and stress to tortoises of flap traps compared to pitfall traps offset their higher cost in terms of materials and construction labor.

Acknowledgments.—Field assistance was provided by Barbara Almario, Dave Berish, Julie Burford, Deborah Burr, Cameron Carter, Chip Deutsch, Don Francis, Courtney Hooker, Matthew Kaunert, Anthony Lau, Cliff Leonard, Rio Throm, Allan Woodward, and Susan Woodward. Jan Boyett, Bland Crowder, Thomas Devitt, Craig Guyer, Allan Woodward, and an anonymous reviewer reviewed the manuscript. We appreciate receiving permission to trap from Plum Creek Timber Company.

An Inexpensive, Minimally Invasive Method for Sampling Gastrointestinal Tract Bacteria in Snakes

Gastrointestinal tract (GIT) microbiota perform important functions and provide multiple benefits to humans and agriculturally important vertebrates and are an essential component of mammalian physiology (Bäckhed et al. 2004, Turnbaugh et al. 2006, Dethlefson et al. 2007). In humans and agricultural animals GIT microbiota protect hosts from pathogens, synthesize vitamins, break down indigestible substances, and influence nutrient uptake and body fat accumulation (Xu and Gordon 2003, Turnbaugh et al. 2006). Our understanding of the diversity and function of GIT microbiota is based primarily on studies of humans, laboratory mice, and agricultural animals but GIT microbiota may be of similar importance to wild vertebrates (Hill et al. 2008).

If GIT microbiota of wild vertebrates perform functions similar those observed in humans and domesticated animals (immunity, digestion, vitamin synthesis) they may in turn influence their survivorship, growth, and reproduction – important life history parameters that affect the population dynamics of all organisms (Stearns 1992). All wild vertebrates are subject to the possibility of periods of fasting due to variation in the availability of food in their environments (McCue 2006). The vertebrates for which the diversity and function of GIT microbiota have been well studied (humans, laboratory mice, and agricultural animals) feed at relatively constant intervals and have diets more uniform in composition than snakes. From a biodiversity standpoint the condition of experiencing periods without food is probably the more general and animals with a steady diet are the exceptions. If we are to understand the role of microbiota in vertebrates in general then their function should be studied in wild animals with variable feeding frequency.

Relatively few studies have examined the diversity of GIT bacteria in wild vertebrates. Several studies have examined the microbial communities present in wild fish GITs (Rawls et al. 2006, Roeselers et al. 2011, Sullam et al. 2012). The majority of studies of GIT bacteria in wild vertebrates have been done on mammals including 4 wild African ungulate species (Nelson et al. 2003), the ceca of wild capybaras (Garcia-Amado et al. 2011), wild parrots (Xenoulis et al. 2010), and developing tammar wallaby's and brushtail possums (Lentle et al. 2006). Gastrointestinal tract bacteria of two wild and one captive snake species have been characterized (Hill et al. 2008, Costello et al. 2010). None of these studies have examined the function of GIT bacteria.

The digestive physiology of snakes is quite different from mammals and birds (Secor and Diamond 2000) which facilitates their use as a model system to expand knowledge of the diversity and function of GIT microbiota. Snakes are capable of surviving much longer periods of starvation than most vertebrates (Wang et al. 2006). How do the snake GIT microbiota respond to periods when the GIT is devoid of food? Does the snake's microbiota contribute to its ability to rapidly digest large prey items? The answers to these and other questions will broaden our understanding of host-microbe interactions and will shed light on the dynamics and functions of GIT microbiota in wild vertebrates in general.

Few studies have used modern molecular methods to characterize the diversity of gastrointestinal tract bacteria in snakes. Preliminary studies have shown that snake GITs contain microbial communities similar in diversity and species composition to mammals, including humans (Hill et al. 2008, Costello et al. 2010). Hill et al. (2008) quantified the GIT bacterial communities in individual specimens of *Agkistrodon piscivorus* and *Crotalus horridus*. They found that bacterial species diversity and composition was similar to that of mammals and birds and included bacteria from the phyla Firmicutes and Bacteroidetes. Costello et al. (2010) compared the GIT microbial communities of fasted and digesting captive Burmese Pythons (*Python molorus*). They too found that Bacteroidetes and Firmicutes dominated the GIT flora but the structure of the community changed depending upon whether the snakes were fasting or digesting. Bacteroidetes dominated the GIT of fasting snakes but Firmicutes dominated the GIT of digesting snakes. Digesting snakes also contained more diverse microbial communities. Costello et al. (2010) pointed out the potential of snakes as model organisms for studying the function of GIT bacteria and the need for the development of a non-lethal procedure for sampling microbiota in the snake GIT.

Because snake GITs are a relatively straight tube it should be possible to sample the GIT microbiota without injuring the snake by inserting some type of device into the cloaca and anteriorly to the intestine. The ability to sample GIT microbiota without injuring the snake would further enhance the utility of snakes as a model organism for studies of diversity and function of GIT bacteria. In humans GIT bacteria have been sampled through the use of an endoscope (Knutson et al. 1982) but such a device is too large to be used in most snakes. In the present study we test the effectiveness of two versions of a minimally invasive sampling device for characterizing the bacterial communities in the gastrointestinal tracts of juvenile Prairie Rattlesnakes.

Materials and Methods.—The five, 2-year old juvenile Prairie Rattlesnakes (*Crotalus viridis*) we used in this study were captive raised offspring of snakes collected from South Dakota and North Dakota in 2008 and 2009. They had been used for laboratory experiments on starvation and metabolic rates but had been on a normal (non-starvation) diet for six months prior to

our study during which time they were fed laboratory mice approximately once per week and given water *ad libitum*. Prior to sampling for GIT bacteria we measured the snakes for snout-to-vent length (SVL) and total length (TL) using a tape measure with an accuracy of +/- 1% of body length .We weighed snakes on a Sartorius Balance (Model BP31000S) to +/- 0.1 g. Snakes were anesthetized during measuring and weighing as described below so we did not use a squeeze box (Quinn and Jones 1974).

We constructed sampling devices by attaching an absorptive material to the end of a 28 gauge stainless steel wire (Fig. 1). We used two different absorptive materials on the sampling devices. One material was a small amount of cotton swabbing which we attached to the wire by doubling the wire back and twisting it around the cotton. The other absorptive material was a small, commercially available, dental hygiene brush (Go Betweens®, Proxabrush Refills®, Sunstar America Inc., Chicago, IL). We attached the wire end of the brush to the sampling device wire using epoxy. We inserted absorptive ends of the wires into 20 cm pieces of teflon tubing (1/8 inch outer diameter) and positioned the end with the absorptive material close to the end of the tube. The end of the Teflon tubing containing the absorptive material was sealed shut with molten paraffin wax. We sterilized the completed sampling devices by exposure to UV light (LABCONCO Class II Biosafety Cabinet, LABCONCO Corporation, Kansas City, MO) for 30 minutes using the protocol described in Cone and Fairfax (2003) and the functioning of the UV hoods are verified once per year.

Prior to sampling we induced a deep plane of anesthesia in snakes using inhalation of isoflourane at a dosage of 2 ml/kg snake body weight. The Isoflurane was volatilized in a small chamber that enclosed the snake's head, but also allowed ample ambient air to enter. We then sampled the live snakes for GIT bacteria using two different versions of our device. Each time we inserted our device into the cloaca and pushed it anteriorly until resistance was encountered. We randomized the order in which the two device types were used to sample snakes. The device was not lubricated. We measured the distance to which the device was inserted as distance from the snout so that we could determine which portion of the GIT was sampled (eg. posterior small intestine, anterior large intestine etc.) by a *postmortem* dissection and so we could resample the same area by dissection. Once the anterior end of the sampling device was in position we held the Teflon tube in position and pushed the wire anteriorly, forcing the absorptive material through the paraffin seal and into the lumen of the snake's GIT. We used a pair of pliers to move the wire because the absorptive end of the sampling device fit somewhat tightly in the tube and did not move freely. We exposed the absorptive material to the lumen for several minutes so it could absorb intestinal materials. We subsequently pulled the wire posteriorly and into the Teflon tube and withdrew the entire device from the intestine and cloaca. We cut the absorptive material from the wire with a pair of pliers which had been sterilized in ethyl alcohol and placed it in a 15 ml centrifuge tube containing 2 ml of distilled water for later analysis for microbial DNA. We stored the samples at -20° C until extraction of genomic DNA the next day.

After sampling we euthanized each snake by decapitation (while still under deep plane anesthesia), dissected the gastrointestinal tract, and located the region of the intestine that was previously sampled by measuring the distance from the snout. We inspected the region of the intestine that had been sampled for any damage possibly caused by sampling and then removed a two cm section of the intestine which included the area sampled. We then gently squeezed the contents of the removed piece of intestine into a sampling vial containing 2 ml of distilled water and stored the samples at -20° C.

We analyzed all samples for bacteria by extracting the DNA, amplifying the gene for the 16s small ribosomal subunit, and analyzing PCR products by denaturing gradient gel electrophoresis (DGGE) according to methods outlined in Hill et al. (2008). Denaturing Gradient Gel Electrophoresis is an established method for characterizing bacterial communities (Ercolini 2003). Bands were visualized under UV transillumination and total number of bands and band similarity among lanes was analyzed using Quantity One gel analysis software (Bio-Rad, Richmond, California). The similarity of banding patterns among electrophoretic lanes was calculated using Dice Similarity Coefficients. Dendrograms were created based on the grouping and relatedness between samples (each lane) and the amount of relatedness is indicated by the percentage bar above each dendrogram. We did not attempt to identify bacterial taxa by sequencing the DNA in the electrophoretic bands because our goal was only to compare the banding patterns obtained by the different sampling methods. This approach assumes that bands from separate samples in similar positions on the gel are the same bacterial species.

Results.—Snakes averaged 46.1 cm SVL (range 39.7 to 49.5, SD = 4.0), 49.3 cm TL (range 42.3 to 53.5, SD = 4.4), and 68.3 g in weight (range 53.6 to 96.6, SD = 18.3).

We successfully sampled the GITs of all snakes using both types of sampling device. All 10 sampling devices were reliably inserted to the level of the anterior large intestine at which point bends in the intestine prevented further anterior movement. *Postmortem* dissections showed no evidence of injury to the snake GIT as a result of our sampling.

Electrophoretic gel lanes from our samples contained an average of 20.5 bands (range 18 to 23, SD = 1.7) as determined by the gel analysis software (Fig. 2). The three sample methods (device with brush, device with cotton, and dissection) had an average of 19.2 bands in common (range 18 to 20, SD = 0.8, Table 1). Dice Similarity Coefficients indicated that the samples obtained by the three different methods from the same snake specimens clumped together and were approximately 88% or more similar (Fig. 3).

Discussion.—Results of our study indicate that our sampling devices are useful to sample and characterize the snake GIT microbiota non-lethally, and without doing harm to the snake. Electrophoretic banding patterns from samples from both our minimally invasive sampling devices were very similar to those obtained by dissection (Figures 2 and 3) and thus appear to provide an adequate sample of GIT microbiota. No consistent differences were found in the results from the cotton vs. brush absorptive materials (Table 1) and we recommend using sampling devices constructed with the cotton absorptive ends because they are cheaper and simpler to prepare and are also probably less abrasive on the snake GIT than the brushes.

Some differences were observed in samples obtained from the same individual snake using different methods. Several specimens obtained using our sampling devices had different banding patterns than those obtained by dissection. It is possible that bacterial species present in the posterior region of the large intestine or cloaca, but not in the anterior region, were picked up by the sampling devices as they were withdrawn from the snake because the end of the Teflon tube was not sealed during withdrawal. There may be some minor differences between the affinity of bacteria or intestinal fluids for the different absorbent materials

TABLE 1. Electrophoretic banding patterns from samples of gastrointestinal tract bacteria from 5 juvenile *Crotalus viridis* (a–e) obtained by three different methods (as in Fig. 2). Numbers under columns for the different sampling methods show the number of bands unique to each sample compared to other samples from that individual snake. "Bands in Common" shows the number of bands in common to all samples from each individual snake.

Snake ID	Dissection	Brush	Cotton	Bands in common
a	2	2	2	18
b	1	2	3	20
c	1	0	0	19
d	0	4	0	19
e	2	0	1	20
			Average	19.2
			SD	0.83666

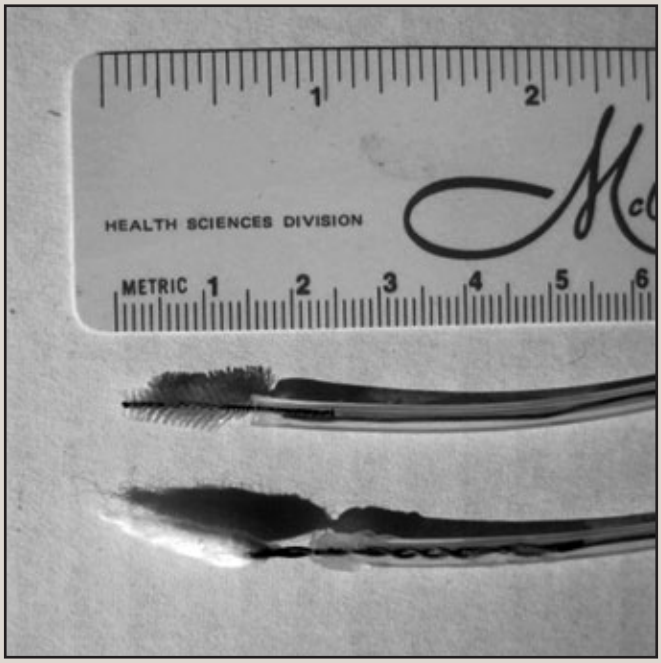

FIG. 1. Details of the two minimally invasive sampling device prototypes used in this study. The upper device contains dental brush absorptive material and the lower device contains cotton swab absorptive material.

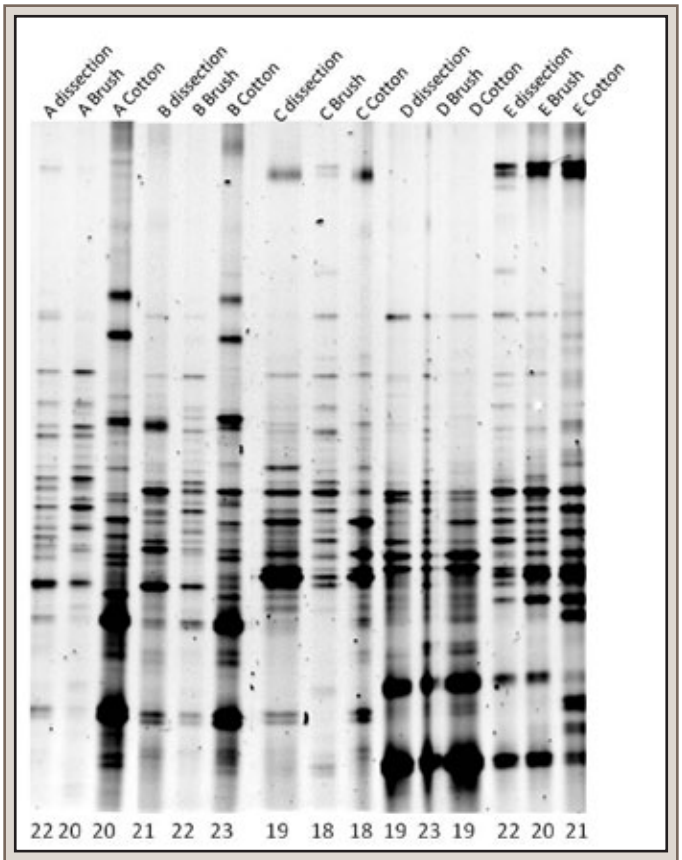

FIG. 2. Denaturing gradient gel electrophoresis banding patterns of bacterial samples collected from the large intestines of five juvenile Prairie Rattlesnakes (A through E) using three sampling methods: Brush = minimally invasive sampling device with brush absorptive end, Cotton = minimally invasive sampling device with a cotton absorptive end, and Dissection = lethal sampling by dissection. Numbers at the bottom of each lane indicate the number of bands as detected by gel reading software.

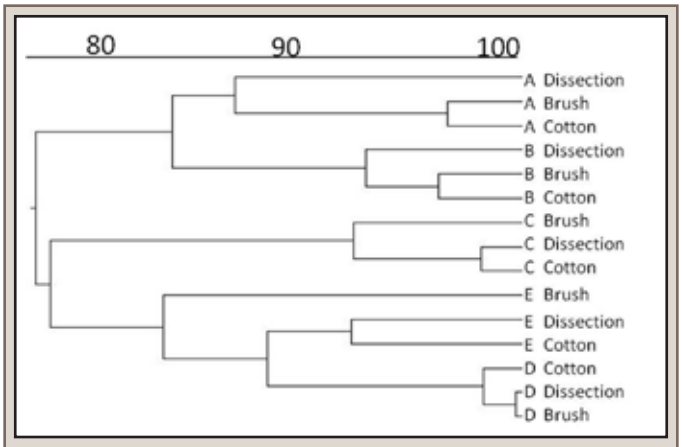

FIG. 3. Comparison of the similarity of the gel electrophoresis banding patterns of bacterial samples obtained from the large intestines of five juvenile Prairie Rattlesnakes (A through E) using three different sampling methods (as in Fig. 2). Scale bar above image indicates percent similarity.

on the sampling devices. The cotton material appears to have different banding pattern than the dissection and brush sampling methods. The cotton material is probably more absorbent than the brush. The brush is probably more abrasive than the cotton. No consistent trends of differences in results among the three different sampling methods were evident (Table 1, Figure 3).

Because we euthanized our snakes immediately after performing our sampling we cannot be certain that the sampling procedure did not have negative effects on the health of the snakes. *Postmortem* dissections did not reveal any damage of the GIT in the regions sampled so we believe no significant negative impacts resulted from the sampling procedure. In addition, snake guts are known for their physiological and morphological flexibility (Starck and Beese 2002, Secor and Diamond 2000). To ingest whole a food item that may be larger than the snake *per se*, requires extreme distensibility. Thus, we do not believe our sampling device poses any significant risk of damage. Nevertheless,

the snake large intestine is relatively thin and injury due to sampling is possible. Future studies should be conducted in which snakes remain alive after the sampling to confirm that the sampling devices do not negatively affect snake's ability to feed or digest food. Our technique represents a successful first attempt at a minimally invasive method to sample GIT microbiota in snakes but there is no doubt that refinements could be made to the device and/or sampling procedure. For example the sampling device should be modified so that the size of the wire is smaller relative to the inner diameter of the Teflon tube so that the wire moves more freely inside the tube.

One limitation of our method is that we could not sample the small intestine because we could not push the sampling device anterior to the large intestine. It is desirable to be able to sample the small intestine which probably contains a different microbial community, with different functionality, than that of the large intestine (Moran 2006; Quigley and Quera 2006). Perhaps the small intestine could be sampled non-destructively by a device inserted through the mouth or by a surgical technique. It may also be possible to insert a sampling device from the cloaca to the small intestine in large snakes (the snakes used in our study were juveniles). Another limitation of our method is that it only samples the bacterial DNA in the lumen of the gut and not necessarily that of the mucosa. Many GIT bacteria are adhered to the mucosa and may not be detected with our method.

Our method will be useful for monitoring changes in snake GIT bacterial communities in the same individuals over time. Bacterial communities are likely to vary in snakes, and other animals, due to variation in diet and frequency of feeding which may in turn may have implications for digestive efficiency and immunity and therefore growth rate, survival, and reproduction. Samples of the GIT microbiota can be obtained using our method whether or not the snake has digesta present in its gut, and in captive or free ranging animals. Our sampling techniques should prove valuable for future studies of GIT microbiota in snakes. The basic ability to sample the GIT microbiota without doing harm to the snake is required for investigations of the functional significance (if any) of snake GIT microbial communities.

Acknowledgments.—We thank Matt Smith for providing the Prairie Rattlesnake specimens used in this study which were offspring of snakes collected under South Dakota collecting permits #51 (in 2008) and #4 (in 2009), and North Dakota permits #GNF02512777 (in 2008) and GNF02599962 (in 2009). The snakes were housed with the approval of the University of Arkansas' Institutional Animal Care and Use Committee (Protocol #08042). Handling procedures for our experiment were approved by the University of Arkansas' Institutional Animal Care and Use Committee (Protocol #10043). Partial funding for this project was obtained from a USDA Food Safety Consortium Grant for SR and partial stipend support for SP from the University of Arkansas Cellular and Molecular Biology Program.

Effectively Sampling Louisiana Diamondback Terrapin (*Malaclemys terrapin*) Populations, with Description of a New Capture Technique

The Diamondback Terrapin (*Malaclemys terrapin*) inhabits coastal salt marshes, estuaries, bays, mangrove swamps, and tidal creeks from Massachusetts to Texas, USA (Ernst and Lovich 2009). Within Louisiana, collection localities are primarily from the eastern coastal marshes including St. Mary, Terrebonne, Plaquemines, St. Bernard, Orleans, and St. Tammany parishes (Dundee and Rossman 1989). There are limited records from the southwestern part of the state, with only a few collections from Iberia (Avery Island, three specimens; Marsh Island, one literature record), Vermilion (University of Louisiana-Lafayette Biological Field Station, one specimen), and Cameron parishes (outlets of Mermentau and Calcasieu rivers, seven specimens; Dundee and Rossman 1989, HerpNet Database Search, www.herpnet2.org, accessed 24 Feb 2012). Most of these records are from opportunistic encounters. Furthermore, none of the records came from Rockefeller Wildlife Refuge (RWR), which appears to have suitable brackish/salt marsh habitat.

Rockefeller Wildlife Refuge is a 30,700-ha coastal refuge in southwestern Louisiana (Cameron and Vermilion parishes) that is managed by the Louisiana Department of Wildlife and Fisheries. Approximately 60% of the refuge is comprised of intermediate salinity marsh units (impoundments), while the remaining 40% is tidally-influenced brackish and saline marshes. Along with providing seemingly suitable tidal marsh habitat for terrapins, there is also no commercialization of fisheries species on the refuge (including Blue Crabs, *Callinectes sapidus*) and the use of commercial or recreational crab traps is not permitted. This is important when considering this study site relative to the growing body of literature from other sites that have documented the impacts of crab traps and the crab fishery on Diamondback Terrapin populations (Dorcas et al. 2007; Gibbons et al. 2001; Grosse et al. 2009, 2011; Hart and Crowder 2011; Roosenburg et al. 1997).

A number of techniques have been used to capture terrapins with varying success throughout their range, including trammel nets, seines, trawls, modified and unmodified crab traps, dip nets, and manual searches for individuals on nesting beaches, in marshes, and in mangrove swamps (Table 1). Fyke nets with leads (Crowder et al. 2000; Roosenburg 1992) have also been used successfully to capture terrapins in Maryland and North Carolina, although there is no information about capture rates with this method. There are considerable differences in marsh types throughout the range of terrapins, and therefore, different methods may be better suited to certain habitat types, achieve greater results, or be more time- and cost-effective in these differing habitats. Within Louisiana marshes, there have been no extensive population studies on terrapins, with no described methods to reliably capture individuals.

A recent survey of 168 researchers with terrapin research backgrounds (across the 16 U.S. coastal states which have terrapins) found that no researchers thought terrapin populations were increasing in their states, while 14.8% said terrapins were stable, 29.6% said declining, and 55.6% responded that the status was uncertain (Butler et al. 2006). Louisiana respondents were unanimous that the status of terrapins was unknown within the state. Further, Butler et al. (2006) found that respondents from Louisiana considered the greatest threat to terrapins to be commercial harvest and that the most needed action within the state would be to "initiate field studies, distribution surveys, and habitat identification." Currently, there is no federal protection for terrapins, but they are considered vulnerable or imperiled in many states and listed as S2/Imperiled within Louisiana (Lester et al. 2005).

Descriptions of dependable capture methods are needed so researchers can begin to determine terrapin distribution and population status within Louisiana. This is relevant due to the 1) the continued loss and alteration of coastal marsh habitat; 2) unknown impacts of recreational and commercial crab fisheries; and 3) potential impacts of the 2010 Deepwater Horizon oil spill on coastal marsh habitat and terrapin populations. Herein, we compare capture efficiencies for previously described techniques and present a description of a new technique that may be applicable throughout the range of the species.

Methods.—We sampled for terrapins at seven localities on RWR during the spring and fall of 2011. All sites are classified as coastal brackish or saline marshes with all having current or historical connections to the Gulf of Mexico via tidal creeks or canals. Dominant marsh vegetation types were Oystergrass (*Spartina alterniflora*), Saltgrass (*Distichlis spicata*), and Hog Cane (*Spartina cynosuroides*), with water salinities during the study ranging from 7–31 ppt. Semi-diurnal tides occurred at the sites on RWR, with a tidal range from -0.326–1.051 m during the study (data from closest tidal station at Calcasieu Pass, approx. 58 km W of RWR; http://tidesandcurrents.noaa.gov/; accessed 3 July 2012). At many sites in the eastern portion of the refuge, there are a diverse number of available habitats including tidal channels, large tidal ponds, and some areas of broken marsh (i.e., marsh areas with a mix of many small ponds or pools).

We sampled terrapins at sites across the refuge from 21 March–2 June 2011. We sampled at each site for three consecutive days with baited modified crab traps, unbaited fyke nets with one or two lead nets, and we also used airboat manual searching. Sampling was also done in September and October 2011 using airboat manual searching only.

At each site, we fished 10 modified crab traps for three consecutive days and each trap was checked once per day for captures. Each crab trap was equipped with a live net extension and floats to prevent terrapin drowning (similar in design to Butler 2000 and Mann 1995). Each standard crab trap had a 3-m PVC pipe fixed through the live net, trap, and marsh bottom for

support. Traps were baited with Striped Mullet (*Mugil cephalus*) and/or Gulf Menhaden (*Brevoortia patronus*), with each trap checked once per day. The efficiency of this method is described in capture per trap day.

Second, we used six double-throated hoop nets with diameters of 0.9 m; three nets had a single 7.6-m lead net and another three had two 7.6-m lead nets or "wings" (hereafter referred to as fyke nets; The Fish Net Company, Jonesville, Louisiana). The lead nets had floats affixed to maintain position at the water's surface, while weights on the bottom held the leads in a stretched position. The lead nets were stretched completely across tidal creeks and both ends were tied to 3-m steel pipes that were driven into the marsh bottom on the edges of creeks. This method stabilized the net, while it also prevented terrapins from going past the nets. Floats were also placed within the hoop net portion to prevent drowning of captured terrapins. Fyke nets were used in tidal channels and canals with widths ranging from 4.1–17.3 m, with the latter being the largest channel effectively trapped with the double-lead fyke net. At each site, we attempted to check nets every day for two or three consecutive days; this was sometimes not possible due to severe weather conditions. Total effort with fyke nets ranged between 8 and 18 total net days at each site. The efficiency of this method is described in terrapin captures per net day.

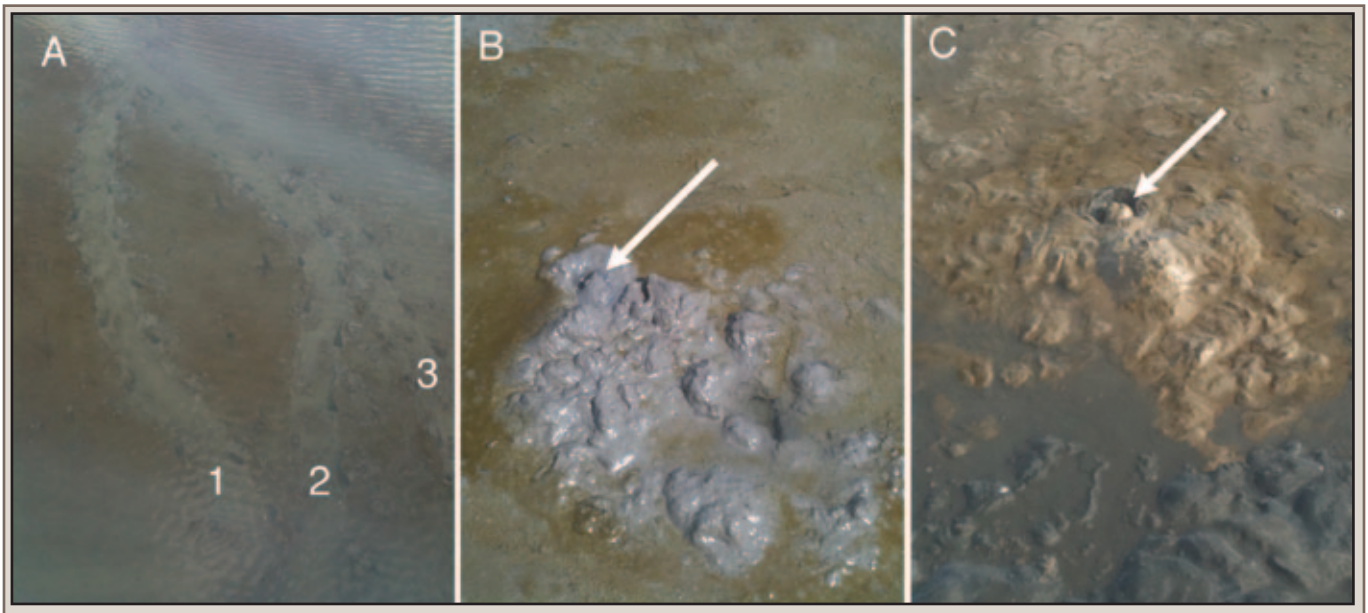

FIG. 1. Three different terrapin tracks on a tidal mud flat (A) and examples of terrapin "mud burrows" (B, C).

Third, from an airboat we conducted visual surveys for terrapins and terrapin sign near our trapping sites. During low water periods, particularly those associated with low tides or strong northerly winds, tidal ponds and mud flats were visually searched from the airboat while it was steered in a "zigzag" or "hairpin" fashion (with <20 m between search paths). Both the airboat driver and passenger looked for terrapins and their tracks or burrows. Terrapins were found by a) following recent terrapin tracks impressed on the bottom of tidal ponds (Fig. 1a), b) searching for "mud burrows" (Figs. 1b, 1c), or c) catching turtles opportunistically while they were moving. When tracks were found, they led us to either the edge of the pond and into the marsh (a lost trail and unsuccessful attempt), to an active terrapin, or to a terrapin burrow. Once a burrow was observed, either by following tracks or detection of the burrow by an observer, the passenger probed the suspected burrow with a long metal pole, feeling for the hardness of a terrapin shell. If a terrapin was found in the burrow, the pole could be used to pry the terrapin from the burrow. Occasionally, burrowed turtles would protrude their heads out of their burrows or above the surface of the water as the airboat entered or left a tidal pond. This permitted easy location of terrapins, which could then be extracted from their burrows by hand. Presumably burrowed terrapins are curious about the airboat, probably due to the noise or vibration. The efficiency of this method is described in captures per boat hour due to the divided duties of the operator between driving and searching for terrapins.

For each captured individual, we recorded capture method, sex, midline plastron length (PL, to the nearest mm), and whether the individual was a recapture. Since little is known about the timing of reproductive maturity in Louisiana terrapins, we considered juveniles as <9 cm PL for males and <13.2 cm PL in females based on previous terrapin studies (as cited by Ernst and Lovich 2009). Terrapins were permanently marked using drill holes on the marginal scutes according to Cagle (1939) and also PIT tagged (12 mm; Biomark, Inc., Boise, Idaho). Individuals were brought to the lab for a related dietary study and were released the following day at their capture locations.

We used a *t*-test to determine if catch rates (terrapins per net day) were equal for single- and double-lead fyke nets. Chi-square tests were used to determine if sex ratios were equal for fyke net captures and manual searching captures. We also used *t*-tests to determine if PL was equal for the capture method used (fyke nets vs. airboat manual capture); males and females were analyzed separately due to pronounced sexual size dimorphism in the species. JMP 8.0 (SAS Institute Inc., Cary, North Carolina, http://www.jmp.com) was used for all statistical analyses with significance levels of $p < 0.05$.

Results.—Trapping methods varied in success and we abandoned modified crab traps after one site due to zero captures (in 30 trap-days). Fyke nets with leads captured a representative sample of both sexes and juveniles (20 M, 22 F, 10 juv.) in 104 total net days. The overall CPUE of fyke nets at all sites was 0.5 terrapins/net day (max. of 7 terrapins in a single net), with site differences ranging from 0–2.1 terrapins/net day (0.06, 0.1, 1.0, 2.1, and three sites with zero captures). Since we are unsure if terrapins occurred at the three sites without a capture, the average CPUE was 0.8 terrapins/net day if only sites with terrapin captures are included. From the sites where terrapins were captured, there was no significant difference in the capture rates between fyke nets with single or double leads ($t = -0.57$, $P = 0.57$). Airboat visual searching was most productive (8 M, 60 F, 14 juv.), with 3.64 terrapins captured per boat hour (82 captures including 3 recaptures in 22.5 boat hours; Fig. 2).

Terrapin sex ratios did not differ from equality for fyke net captures ($\chi^2 = 0.36$, $P = 0.55$), while airboat manual captures were significantly biased toward females ($\chi^2 = 46.1$, $P < 0.0001$; Fig. 2). Mean PL was not significantly different between the two capture methods for males ($t = 0.47$, $P = 0.65$) or females ($t = -0.48$, $P = 0.64$; Fig. 2). However, it is noteworthy that the six largest females (>19.0 cm PL) were manually captured from an airboat.

Discussion.—We abandoned the use of crab traps after the first site primarily due to the lack of success with this method. The first site had the highest number of terrapin captures within tidal creek and surrounding ponds using the other two methods (37 by fyke net, 50 manual searching). Therefore, the lack of captures in crab traps was not due to a lack of terrapins in the vicinity. Another reason we discontinued the use of modified crab traps was that they were bulky and difficult to transport in

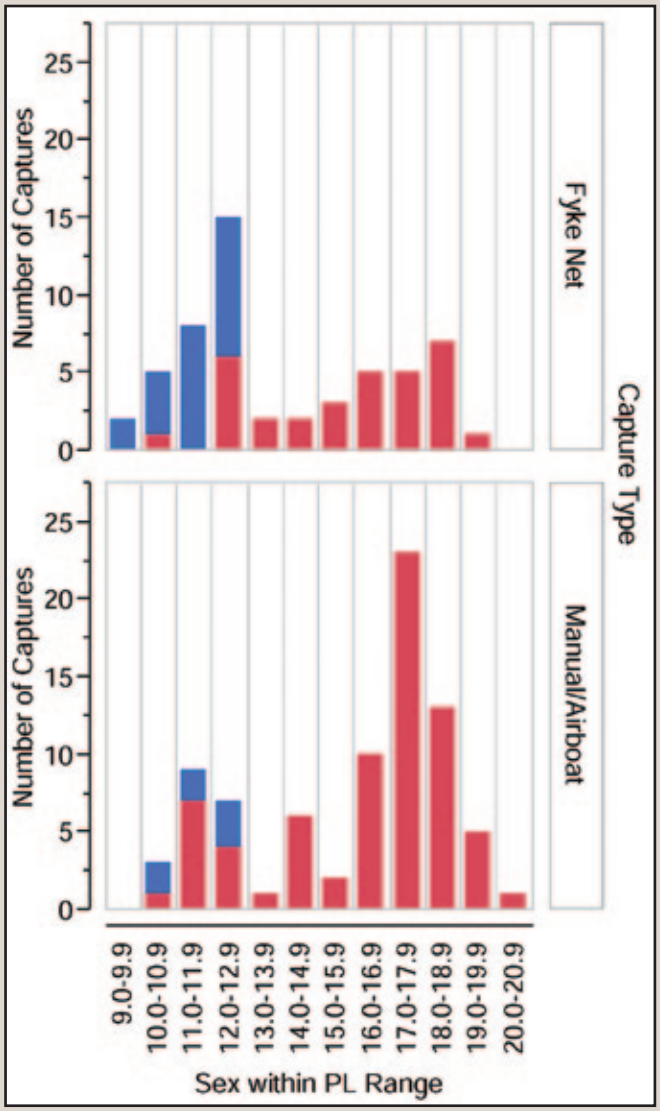

FIG. 2. Diamondback Terrapin (*Malaclemys terrapin*) plastron length comparisons for both sexes (male: blue, female: red) by capture method.

the airboat, our only means of access to field sites. In addition, two of the traps floated away from their sampling location (likely due to tides or wind) even with the support pipe fixed through the trap and into the marsh bottom. Similarly designed modified crab traps have been used with moderate success in Florida (Butler 2000, 2002) and Mississippi (Mann 1995), while other studies have experienced similar low to moderate success rates with crab traps or modified crab traps throughout the range of diamondback terrapins (Table 1).

Fyke nets provided an unbiased sampling method, with a relatively high CPUE compared to other studies and sampling methodologies. It took some time and effort to set and adjust the nets to changing marsh conditions (i.e., tide levels, reattaching nets following terrapin removal), but less effort than using the modified crab traps. Based on our results and observations, single-lead nets are preferable, however they must have strong enough mesh (>#15 size) to prevent tearing by large captured fish, particularly Alligator Gar (*Atractosteus spatula*). Lead nets also need sufficient buoyancy to keep them at the surface. Double-lead fyke nets did not catch more terrapins than single-lead nets and they were less efficient than single-lead nets, in both the longer time it took to set them and the higher cost. Fyke nets have been used successfully with other terrapin studies in Maryland (Roosenburg 2004), with varying levels of success depending on the time of year and length of lead net (W. Roosenburg, pers. comm.). A drawback to our method is that the lead net is stretched completely across tidal creeks and may prompt indignation from boaters if they experience difficulty in accessing tidal creeks. We did not have this problem due to the difficulty in accessing remote tidal creek sites on RWR, but this possibility should be considered before researchers use this method in public waters.

Visual searching was achieved primarily from an airboat moving through the marsh and tidal ponds. This method was more productive than expected, but it was most successful during low tide periods, when marsh water levels were low and shallow tidal ponds were easy to search from an airboat. Similarly, Haskett (2011) had success when searching manually for terrapins in tidal creeks and shallow ponds at low tides, while fishermen noted that they could search for terrapin "mounds" in shallow, still-water bays following passage of a cold front in winter (T. Mann, pers. comm.). Even though manual searching was female-biased, there was no difference in size for males or females caught with the two capture methods (fyke net vs. manual searching), thus making population comparisons easier when combining capture data. Airboat manual searching also had a higher CPUE than fyke net captures, but when time spent checking and setting nets is considered, CPUE would be considerably greater for airboat manual searching than for fyke nets.

For the many advantages of searching with an airboat, there are also several potential drawbacks to using this method: 1) female-biased capture rates, 2) need for low-water conditions in the marsh (either tide- or wind-driven), 3) difficulties in spotting or determining terrapin tracks and burrows, and 4) the expense of operating an airboat. Airboat manual searching was found to be female-biased, likely due to the larger size of the tracks and larger mud burrows that females make because of their larger body size (in length, height, and mass) compared to males. Second, optimal low tide/low water levels (typically <15 cm or when pond bottom is visible) are needed to search effectively for terrapins from an airboat. We often consulted tide charts to determine days when tides would be the lowest, but southerly winds sometimes counteracted the low tides and pushed more water into the tidal marshes. Conversely, strong northerly winds sometimes evacuated more water from the marsh than low tide levels. If water levels were too high in tidal pools, water conditions made it more difficult to see terrapins in the water due to excess turbidity. A larger wave was also generated by the airboat during high water which made capturing active terrapins more difficult. Third, it was initially difficult to recognize the difference between wading bird, crab, and terrapin tracks in pond bottoms, as well as distinguish between terrapin mud burrows and those of other mud-burrowing organisms (i.e., Blue Crabs). However, once we developed our "search image" for terrapin mud burrows, it became relatively easy to locate them. Last, the use of airboat equipment is expensive due to the maintenance costs and the increased cost of fuel (either aviation fuel or premium gasoline). If an airboat is not available to researchers, the user fees for an airboat and skilled airboat operator generally range between US $600–800 per day (P. Trosclair, pers. comm.). To our

knowledge, this is the first study to use airboats to search for and successfully capture terrapins.

In comparing our capture efficiency results with those reported in other terrapin studies, both airboat manual searching and fyke net efficiency are generally higher than in other studies; airboat manual searching has the highest reported CPUE of any terrapin study or capture method described (Table 1). These two techniques could be superior capture methods for terrapins in southwestern Louisiana, but it is also likely that the high CPUEs could be directly related to high terrapin densities, as we had very few recaptures during the study. Further, we saw no evidence of active commercial or recreational crabbing on the refuge. Sizable terrapin populations could be present on RWR due to: 1) the aforementioned lack of commercial fisheries, 2) lack of crab trapping, 3) the large available tidal marsh habitat, and 4) the diversity of marsh habitat types on RWR. Future use of these methods off the refuge would be valuable in order to better document the distribution and abundance of terrapins in southwestern Louisiana, while also documenting the interactions of the commercial crab fisheries on terrapin populations.

Acknowledgments.—We thank C. Baccigalopi and R. Hebert for their assistance in operating the airboat, while G. Nunez provided great airboat maintenance throughout the study. The comments and suggestions by J. Butler, T. Mann, and two anonymous reviewers greatly improved this manuscript. Louisiana Department of Wildlife and Fisheries approved of this project and we complied with all applicable animal care guidelines as outlined by the Society for the Study of Amphibians and Reptiles. Rockefeller Trust Fund provided funding for this project, as well as the costs of airboat equipment and maintenance.

A New, Harmless Mesocosm Design for Field Rearing Ranid Embryos and Determining Clutch Sizes

As an important life history trait of amphibians, clutch size has been frequently used in a variety of ecological studies (e.g., Cooper et al. 2008; Morrison and Hero 2003; Woodward 1987). Since size and shape of egg masses vary considerably among amphibians (Duellman and Trueb 1994; Wells 2007), different methods may be required for counting eggs in taxa differing by these traits. The majority of temperate ranid frogs are characteristic for their large and compact egg masses (Arnold and Ovenden 2002), with a certain proportion of eggs unapparent within the center of the egg mass (Karraker 2007). In such cases, it is problematic to accurately count the eggs without harming them, and this usually requires manipulating the clutches (Ponsero and Joly 1998; Woodward 1982). It is clear that such handling can damage the disrupted eggs directly or increase their sensitivity to microbial or fungal attack (e.g., Ficetola and De Bernardi 2009; Karraker 2007). On the other hand, mere visual estimation may under- or overestimate clutch size because of difficulties associated with the counting of interior eggs (Karraker 2007).

Methods.—Here we present a new, simple device that was created and tested during studies on the Agile Frog, *Rana dalmatina,* in the North Bohemian brown coal basin in the Czech Republic (Smolová et al. 2010; Vojar et al. 2008). Our device allows for the counting of frog eggs in the field without harmful impact to the clutches. The device is positioned around a clutch and consists of a floating polystyrene ring placed inside fine elastic netting (Fig. 1F). The diameter of the ring depends upon the clutch size of a particular frog species. In the case of *R. dalmatina*, we used rings with an inside diameter of 15 cm. The polystyrene rings are used to hold the device on the water surface. We used nylon pantyhose as netting, which offers many advantages. The stockings are commonly available, inexpensive, sufficiently elastic, resistant to perforation, and, most importantly, they are permeable to water and food for the tadpoles (floating algae, small organic particles) while at the same time impermeable for hatching larvae and their predators. Device preparation is outlined in Fig. 1.

In the case of a clutch attached to a stem, as is often true for *Rana dalmatina* (Rehák 1992), the stem must be carefully cut both below and above the clutch before the device is installed. The stocking should be tied off from above (Fig. 1G), to protect eggs against potential predators (Henrikson 1990). To maintain the same position of the clutch on the water's surface, and particularly when the stem had to be cut off, the device might be attached to a stick. After the larvae hatch, the entire contents of the ring (i.e., larvae, undeveloped eggs and egg jelly) may be transferred to a basin with a little water and examined there. Immediately after their being counted, the larvae together with the original egg jelly should be returned carefully to the same place in the water.

Results.—The device was tested on 193 *Rana dalmatina* egg masses during two breeding seasons, in 2007 (N = 80) and in 2010 (N = 113). Only those clutches from 2010 were protected from above. The hatching success, i.e., the ratio of embryos that developed to hatching to total clutch size, varied significantly between seasons (2007 mean ± SE: 0.86 ± 0.02; 2010: 0.91 ± 0.01; Wilcoxon rank-sum test: $W = 5334$, $p = 0.03$). Even though such inconclusive differences could be due to factors other than egg protection (e.g., environmental conditions that varied between years, inclusion of different individuals in the samples), we observed egg predation by diving beetles (*Dytiscus* spp.) only in the case of unprotected clutches.

Discussion.—Using this device has several limitations. It can only be used for amphibians that spawn separate and compact eggs masses near the water surface, as well as having herbivorous larvae. The method should not be applied in case of clutches placed deeper in the water column. The change of clutch position in a water column can lead to changes in environmental conditions (e.g., water temperature, intensity of UV-B radiation) between the original, deeper location and a new one on the water's surface. This could have possible negative effect on embryonic survival (Pounds 2001). The stocking's inner surface quickly becomes covered by algae and organic particles. Thus, the device provides appropriate food conditions mainly for generalized grazers scraping the substrate (Duellman and Trueb 1994). The method is particularly suitable for ranid frogs. Because cannibalism has been observed in ranid tadpoles (reviewed in Alford 1999), counting should be performed directly after the larvae hatch. Nevertheless, clutch size may be slightly underestimated and hatching success overestimated, as the first hatching tadpoles may eat dying, dead, or decaying embryos.

The main advantages of the method are its reasonable accuracy and simultaneously its relatively non-invasive handling of amphibian clutches. As distinct from other methods, it is not necessary to disrupt all (Berven 1982; Woodward 1982) or even a

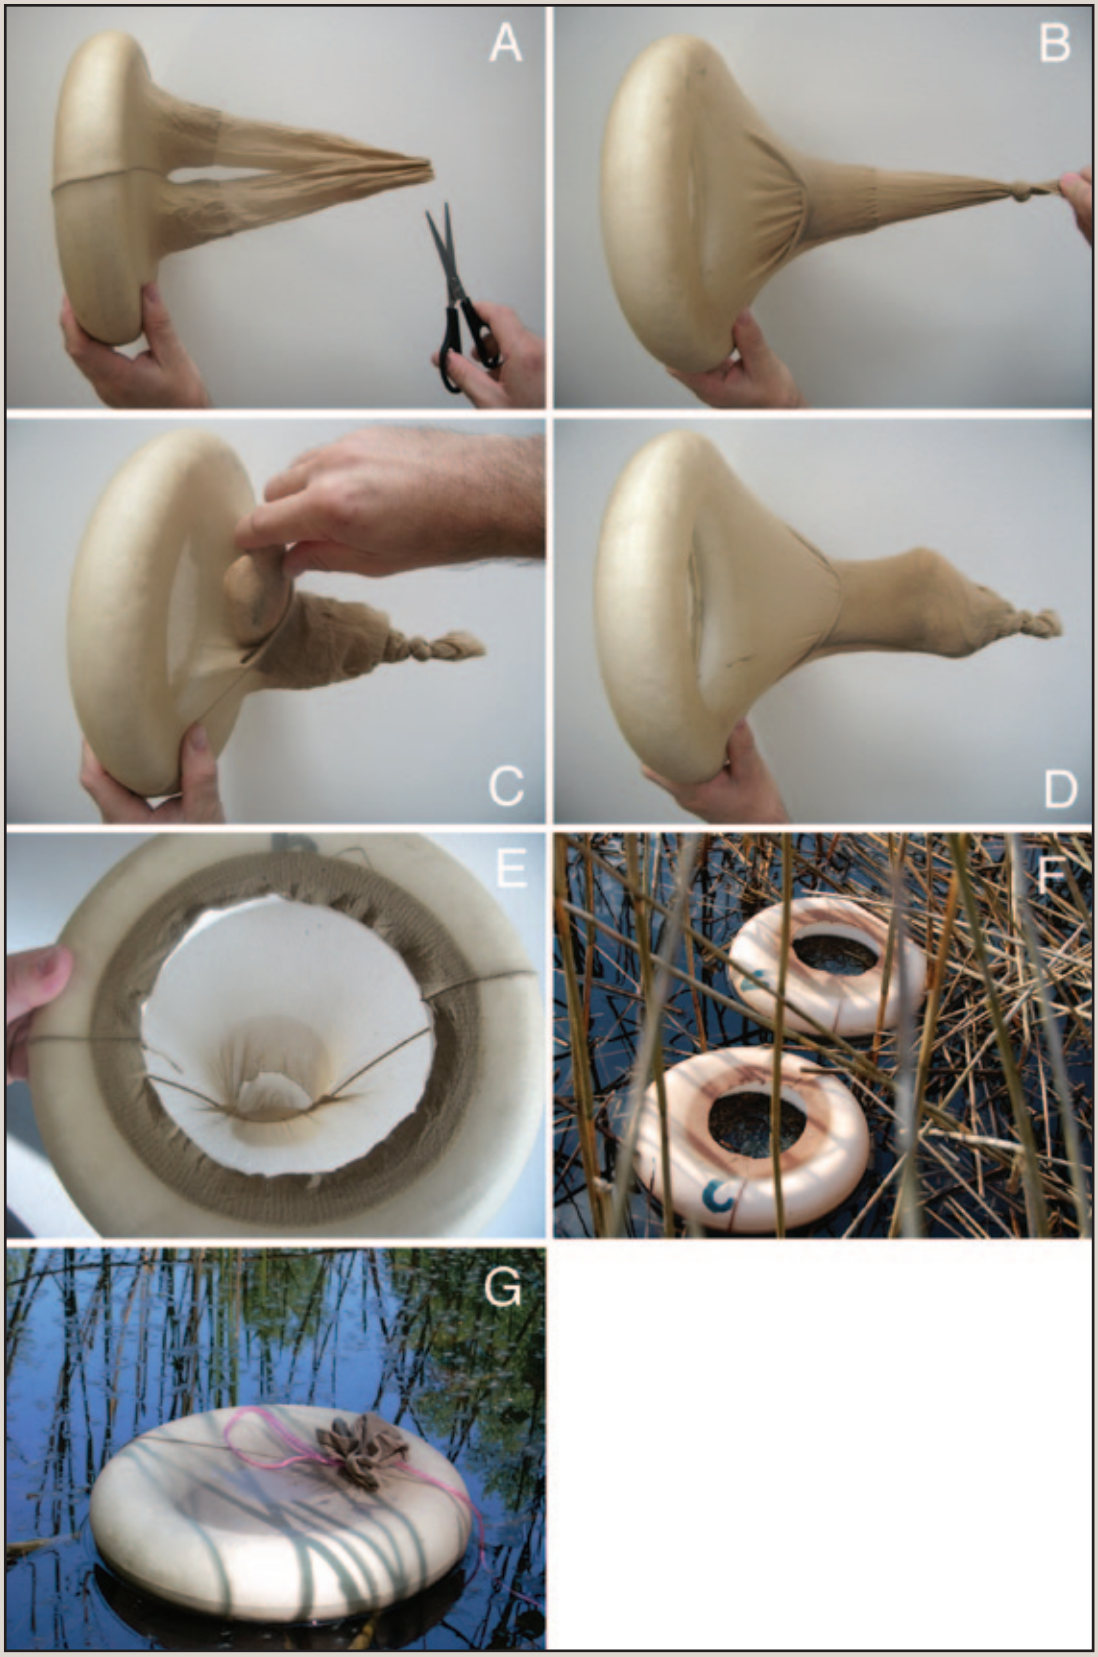

FIG. 1A–G. Device preparation: stocking legs should be cut off about 25 cm below the crotch of the pantyhose (A). One leg is then inserted into the second and both legs are tied into a knot together at the free end (B). A stone is inserted into the pocket thus formed (C). This provides weight (D) and creates sufficient space for a clutch (E). Since this weighting object is inserted from outside of the device (C), it can be later removed without making potentially harmful contact with tadpoles before their counting. The entire device is then positioned around a clutch (F). To protect eggs against numerous potential predators, the stocking should be tied shut from above (G).

part (Ponsero and Joly 1998) of the egg masses. As there is no manipulation of the clutches (except for cutting the stem in the case of stem-attached clutches), the use of floating rings is likely to be more harmless than flattening egg masses (Harris 1980; Karraker 2007) or using standard mesocosms (Skelly and Keisecker 2001).

The method represents a new and inexpensive mesocosm design that allows increased mixing of water, and thus fairly natural conditions. Presented design will be also useful for people who have to hike long distances to research ponds because of the lightweight materials. The device could be deployed in a wide range of ecological studies in a field due not only to its reasonable accuracy but also to its lack of invasiveness. Considering the evident global amphibian decline (Barinaga 1990; Houlahan et al. 2000; Wake 1991), conservation requirements and ethical principles should be strictly followed in amphibian research.

Acknowledgments.—This study was supported by Research Project of the Faculty of Environmental Science, Czech University of Life Sciences Prague, No. 42900/1312/3114 and Research Project of the Technology Agency of the Czech Republic No. TA01020881. Thanks to Kamila Šebková, Jindich Gučík, Magdalena Jílková, and others for help in the field and to Oldřich Kopecký, Gale A. Kirking, and two anonymous reviewers for useful comments on the manuscript. The study was carried out under permit number 00285/LP/2009/AOPK from the Agency for Nature Conservation and Landscape Protection of the Czech Republic.

Rhadinaea "sargenti," a Misspelled Patronym Honoring Commander William M. Sergeant (1902–1983)

The snake *Rhadinaea sargenti* is endemic to east-central Panama, where it was discovered about 1936 during surveys and mapping of the Río Chagres drainage—a watershed critical for lock operations in the Panama Canal. Type specimens are catalogued in the Museum of Comparative Zoology (MCZ) as having been collected by Dr. H.C. Clark, who, however, supplied the material but did not actually collect it. Herbert C. Clark, the first director of the Gorgas Memorial Laboratory (GML), oversaw a snake census in various parts of Panama during 1929–1953 (summary and references in Myers 2003:4–5). Clark's early material sent to MCZ was turned over by Director Thomas Barbour to his student Emmett Reid Dunn for identification. Dunn started visiting GML in 1939 and had access to background information on Clark's census. Later that year Dunn and Bailey (1939) described some species that Clark had sent to the MCZ, including *Rhadinaea sargenti*, which was collected by "Sargent's party." Dunn and Bailey (*op. cit.*: 4) noted that "Mr. W.M. Sargent, head of "B" [survey] party, was especially interested [in the snake census]. His party took 78 snakes, on most of which we have detailed field data."

Unfortunately the name of the engineer "especially interested" in collecting snakes was misspelled. His correct name is William Manuel Sergeant (Fig. 1). Sergeant wrote to Ernest Williams at MCZ in 1978, saying that "Sometime between 1935 and 1938, The Panama Canal conducted a field survey to locate the Chagres River divide [requiring] that machete-men cut over 100 miles of jungle trails along the divide . . . Among the snakes caught by my party was a small non-venomous snake [that] turned out to be a new find and my name (misspelled) was included in the classification." Williams supplied the reference wanted by Sergeant and copied his response to Myers, who picked up on the correspondence, asking Sergeant for further information about his work in Panama. Sergeant provided the following:

> In 1906, at age four years, I left New York for the Isthmus of Panama, where my father was employed by the Isthmian Canal Commission on the construction of the Canal. I returned to the States after graduating from the Canal Zone high school in 1922. I received the degree of Bachelor of Civil Engineering from Louisiana State University in 1929. From 1929 to 1941 I was employed by the Panama Canal on engineering projects, including the construction of the Madden Dam on the Chagres River. Upon completion of the Dam I worked on investigations in connection with the Dam, its appurtenances and its watershed, including the survey to locate and close the gap of the Chagres River divide at the headwaters of its two principal tributaries, the Pequeni and the Esperanza Rivers. Later I worked on the plans for a third set of locks for the Canal.
>
> I resigned from The Panama Canal in 1941 and went on active duty with the Navy. During World War II, I served with the Civil Engineering Corps of the Navy in the Canal Zone, Ecuador, continental United States, Hawaii and the Philippines. In 1946 I was detached from active duty with the Navy and resumed employment with The Panama Canal on engineering studies for a sea-level canal in Colombia and Central America, including several routes in Panama. In 1951 I was assigned to the Panama Canal Company as Supervising Construction Inspector for Government construction contracts in the Canal Zone.
>
> August 1, 1960 I retired from the Panama Canal Company after 32.8 years of Federal service and returned to the United States.
>
> September 1, 1962 I was transferred to the Naval Reserve Retired List with the grade of Commander, after 26.5 years in the Naval Reserve." [William M. Sergeant in letter to Myers, December 14, 1978, AMNH Herpetology Archives]

Much of Sergeant's employment history is corroborated in issues of *The Panama Canal Review* (October 5, 1951; January 3, 1958). We are unaware of publications by him, except for an editorial titled "Our Opportunities" in his 1922 high school yearbook (*The Zonian*, Balboa, Canal Zone); he expanded on the importance of learning Spanish in order for Americans "to get their full share of Latin American trade, which has been practically monopolized by European countries." William Manuel Sergeant was born in Havana, Cuba on August 17, 1902; he died on February 25, 1983.

PHOTOGRAPH COURTESY PANAMA CANAL AUTHORITY

FIG. 1. William M. Sergeant, a Cuban American engineer responsible for the discovery of *Rhadinaea sargenti* during trail-cutting operations in the Panama Canal watershed. This photograph, dated July 15, 1960, was taken a few weeks before Sergeant's retirement.

PHOTO BY ROBERTO IBÁÑEZ D

FIG. 2. *Rhadinaea sargenti* Dunn and Bailey, a distinctive species roughly 300 mm in total length. This little snake is known only from central Panama, where it occurs east of the Panama Canal in low, forested mountains designated as the "Chagres Highlands" (Myers et al. 2012). The uniformly blackish sides are diagnostic; *R. sargenti* is most closely related to *R. vermiculaticeps* (Cope)—the generic type species, which occurs in highlands west of the Panama Canal.

Rhadinaea sargenti is a rare snake (Myers 1974:162–163, 245; Ibáñez et al. "1994" [1995]). It has been reported in print mostly from specimens obtained by Sergeant, whose "B" party "took five of the six specimens" (Dunn and Bailey 1939:4, 11). The sixth specimen, a paratype from the Piedras-Pacora ridge, may have been obtained by the "E party." The holotype and three paratypes are in the Museum of Comparative Zoology (MCZ 42764, 42787–42789); two other paratypes collected by Sergeant's party might have been discarded (see below). An additional specimen from the Panama snake census—not a type—was retained by Clark for his GML collection (Myers 1974:245). Five new specimens, however, have been collected in recent decades (unpublished, including Fig. 2).

The 12 known specimens come from localities widely scattered in low mountains east of the Panama Canal "in humid tropical forest that lies on the wet side of evergreen seasonal forest" (Myers 1974:162). These mountains, unnamed on most maps, are the "Chagres Highlands," which provide a lower montane forest refuge for some rare snakes and frogs. The specimen in Fig. 2 is from the northeastern periphery of the Chagres Highlands (at 9°19'45"N, 79°9'12"W); this geologically complex uplift contains the important Chagres drainage as well as more eastern streams that drain directly north to the Caribbean Sea or south to the Bay of Panama (Myers et al. 2012).

Dunn and Bailey (1939:11) included in the original description two uncatalogued heads; these are paratypes but their disposition is unknown to us. Most of Clark's Panama Snake Survey was based on heads. As summarized by Myers (2003:4), "Unfortunately, over 90% of the [13,745] GML specimens were apparently discarded after Dunn's study, except for whole specimens and selected heads especially of rare species that were placed in major museums. Fewer than 1000 specimens with data were saved from the Panama snake census, which spanned a quarter of a century."

Dunn was an influential herpetologist who left an important body of research. He, however, was not the most careful worker and left two misspelled names for the Panamanian fauna: *Rhadinaea* "*sargenti*" and *Colostethus* "*panamansis*." These cannot be corrected. The last name was an incorrect latinization that Dunn himself later emended to "*panamensis*" (Grant et al. 2006), but by a vote of 13 to 11 the International Commission of Zoological Nomenclature ruled that Dunn's original spelling must be maintained (ICZN 2008: Opinion 2195).

Myers had explained to Sergeant that "rules of nomenclature consider the stability of a name to be more important than the correctness of its formation." Myers promised to point out the misspelled name in a future supplement to his *Rhadinaea* monograph. That planned "supplement" was superseded by other publications on the genus, but we are pleased finally to note the misspelling and to honor Commander Sergeant's service to his profession and to his country.

Acknowledgments.—Our late colleague Ernest E. Williams called attention to Sergeant's 1978 letter of inquiry and José Rosado supplied information on the MCZ holdings. Grace Tilger obtained dates of Sergeant's birth and death from the U.S. Department of Veteran Affairs Death File. César A. Jaramillo, Daniel Medina, Ernie Osburn, Ángel Sosa, and Kelly Zamudio provided information on new specimens. María G. Bermúdez Kelly and Earl Barber, Autoridad del Canal de Panamá, searched and provided the archive photo of W. M. Sergeant. Patricia J. Wynne finessed and improved the electronic image for Fig. 1.

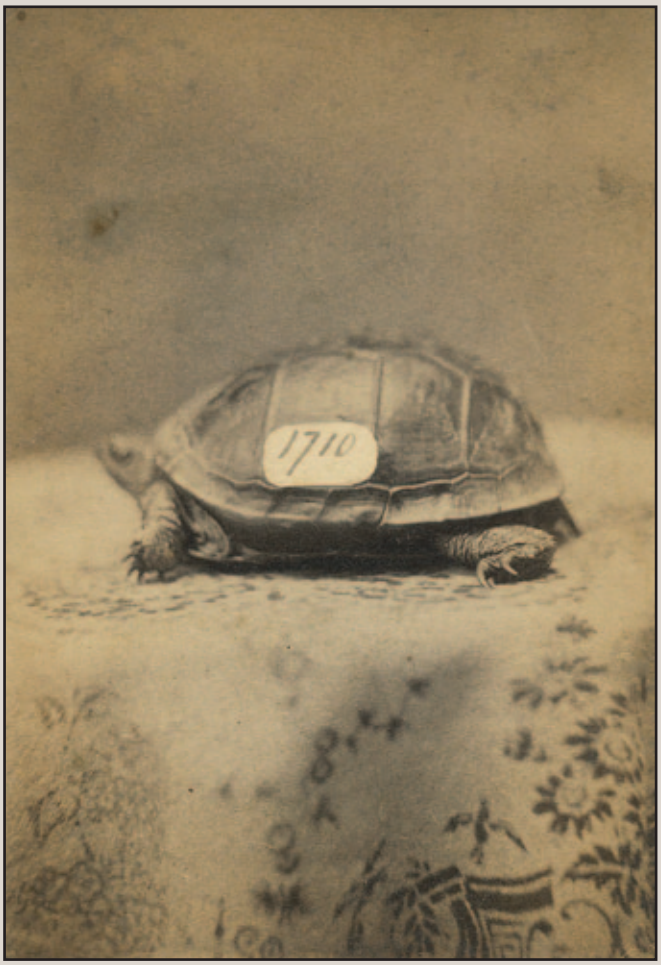
A Chelonian Civil War Veteran

Within the last 15 years, there have been a few accounts published in *Herpetological Review* that document early photographs of reptiles (Table 1). Interestingly, all of these previously referenced photographs were recorded and produced outside of the Americas, and do not feature any species from this continent. Here, I present a very old photograph of a native and highly recognizable North American reptile—the Eastern Box Turtle, *Terrapene c. carolina*.



This peculiar item is a *carte de visite* (CDV)[1] depicting a turtle (apparently alive) in a studio setting (Fig. 1). A photographers' stamp on the verso indicates the CDV was produced by the "Tyson Brothers," of Gettysburg, Pennsylvania. According to William A. Frassanito, the foremost authority on early photography at Gettysburg, the style of this imprint dates the photograph to ca. 1864 (W. A. Frassanito, pers. comm.).

Quaker brothers Charles John Tyson (1838–1906) and Isaac Griffith Tyson (1833–1913) moved from Philadelphia to Gettysburg in 1859, where they opened a photography studio in August of that year. Although they were primarily portrait photographers, Isaac and Charles Tyson (Fig. 2) are perhaps best known for being the first Gettysburg locals to photograph battlefield scenes after the bloodiest conflict of the Civil War. The Tyson brothers' careers, as discussed here, are documented more thoroughly by Frassanito (1995).

After the start of the Civil War, hundreds of soldiers were sent to Gettysburg for training, and the Tyson brothers photographed many of these men in uniform. Even as the infamous battle commenced on the morning of 1 July 1863, Charles continued working at his studio (Fig. 3), racing to furnish portraits for crowds of Union soldiers. In a letter to a friend, Charles recounted his experience during this time in great detail. The following is a passage from that letter, which was transcribed in its entirety by Preston (1892; *in* Frassanito 1995):

> I arose to find Gettysburg swarming with Union soldiers . . . I opened the gallery and went to work, and was kept very busy till near ten o'clock. I had made an exposure, and the room was full. I went into the work-room to finish the picture. When I returned the room was empty . . . to my surprise, all the stores were closed and no one to be seen. . . . I met one of our officers riding up the street, warning all women, children, and non-combatants to leave the town, as General Lee intended to shell it.

Charles' letter goes on to describe how he fled to nearby Littlestown with his wife and a neighboring family, where they stayed until it was safe to return home. Fearing that his house and gallery had been "gutted" by confederate soldiers, once back in Gettysburg, Charles was relieved to find that while his house

TABLE 1. A summary of early photographs of reptiles based on accounts published in *Herpetological Review*. "Year" and "Location" refer, respectively, to when and where an image was recorded. Animals are believed to have been alive when photographs were taken unless otherwise noted.

Year	Taxon	Location	Photographer(s)	Notes	Source
1853	Lace Monitor, *Varanus varius* (two preserved specimens)	Muséum National d'Histoire Naturelle (MNHN), Paris, France	"Bisson Brothers" (Louis-Auguste and Auguste-Rosalie Bisson)	Earliest known photograph of a herpetological specimen	Niekisch (2010)
1857	Nile Crocodile, *Crocodylus niloticus*	Egypt	Francis Frith	First known photograph of a living reptile	Niekisch (2010)
1864	Diamond Python, *Morelia s. spilota* Eastern Blue-tongued Lizard, *Tiliqua s. scincoides* Eastern Water Dragon, *Physignathus l. lesueurii*	Photographer's studio, Sydney, Australia	William Hetzer	Features herpetologist Gerard Krefft	Adler and Cogger (1998)
1865	*Boa constrictor*	London Zoo, London, England	Frank Haes	Features unknown zookeeper	Edwards (1998)

had been ransacked, nothing was "wantonly destroyed." Charles added that the gallery was found "undisturbed," although confederates had taken a barrel of alcohol from the cellar, and an artillery shell remained lodged in the building's brick façade, where it can still be seen today (Fig. 4).

Soon after the battle, the Tysons got back to work. Preparation of their first group of battlefield photographs, produced on 8 x 10-inch plates, was announced 10 August 1863. The brothers continued to manufacture battlefield views for the next few months, until demand waned.

Eventually the Tyson brothers parted ways. Charles had become interested in a nursery owned by his wife's family, and in 1864 purchased one-third of the business. In 1866 Isaac returned to Philadelphia, where he opened his own gallery. Charles gained full ownership of the nursery the next year, and in 1868 he sold the photography business to William H. Tipton and Robert Meyers. (Tipton, who began apprenticing under the Tyson brothers in 1863 at the age of twelve, would go on to become one of Gettysburg's most prominent photographers.)

Reptiles were relatively uncommon subjects for early cameramen, whose conventional repertoire focused on people, landscapes, architectural structures, and the occasional pet cat or dog. The Tyson Brothers CDV discussed here is certainly one of the oldest photographs of a living reptile. Might this image also represent the first photograph of a North American reptile species? The earliest surviving photograph of a turtle? The small, unassuming box turtle would seem like an unusual candidate for either designation, given the availability of larger, more "impressive," and presumably more desirable reptilian subjects (e.g., sea turtles, crocodilians). Indeed, this image differs from most early photographs of reptiles, which feature large animals (e.g., Niekisch 2010), humans (e.g., Adler and Cogger 1998), or often both (e.g., Edwards 1998). Why, then, did the Tyson brothers take the time to photograph a box turtle?

This brings us to the most intriguing—and ultimately perplexing—aspect of this photograph. Inscribed in the center of the negative, so as to be positioned (perhaps inadvertently) on the turtle's carapace, is the number "1710." Unfortunately, I could find no indication on the photograph or elsewhere as to the significance of this number, allowing only for speculation.

One possibility is that the "1710" represents a catalog or specimen number. Perhaps, as some have proposed, this photograph was not offered for sale, but rather belonged to the personal collection of Charles or Isaac Tyson. With respect to his interest in horticulture, might Charles have been documenting some of the local flora and fauna? Others have suggested the photograph could have been produced for the science department at Pennsylvania College (now Gettysburg College). Although these seem like plausible explanations, the high numerical value and unusual placement of the inscription in the photograph cast some doubt on the "catalog hypothesis." In any case, if the "1710" does signify a catalog or specimen number, we expect there to be other photographs in existence with similar numerical inscriptions. Searches of relevant archives have yielded no such images.

Alternatively, the number pictured on this CDV could represent a date. Well into the 20th century, it was common for people to carve initials (or sometimes full names) and dates into box turtles' shells.[2] This practice is evidenced, in part, by countless local newspaper reports dating at least as far back as the early 19th century, that speak of turtles found bearing decades-old inscriptions.

Although it has proven difficult to determine the maximum lifespan of *T. carolina*, there are several reputable accounts of individuals of this species exceeding 100 years in age (Graham and Hutchison 1969; National Park Service 2002), including at least one well-documented record of a box turtle thought to

[2] Names and dates are not the only things people have carved into turtles' shells. On 21 August 1865, local Gettysburg newspaper *The Compiler* reported that a man visiting the battlefield at Culp's Hill discovered a turtle bearing the inscription "Co. A, 102d N. Y." (Company A of the 102nd New York Infantry Regiment). "It was a relic of peculiar interest, as the marking was no doubt done by a New York soldier at the time of battle. Its possessor was highly delighted, and valued the turtle almost beyond price" (Stahle 1865).

be over 150 years old (Belzer 2008). The discovery of an animal considered to be of such great age would certainly explain this photograph's atypical subject matter. A date carved into the turtle's shell, however, might not have shown up clearly in a photograph, perhaps leading the photographer to write the numbers on the negative, where they could be easily seen. Thus, although it would seem unlikely, it is *possible* that the turtle pictured in the photograph was marked in 1710.

Of course, not all dates found on box turtles' shells are thought to be authentic (Dodd 2001; Graham and Hutchison 1969). On 24 August 1870, *The Lancaster Examiner and Herald* reported that an "ancient land turtle" had been found on a farm in East Hempfield Township, Lancaster County (~85 km NE of Gettysburg), bearing the inscription "J. L. 1717." Noting that many of these "apparent relics" had turned up in recent years, the author added, "many of the letters and dates carved on their backs are, no doubt, the work of boys who hoped to dupe persons who discover them afterwards" (Hiestand and Kline 1870).

Aside from youths playing practical jokes, the incentive for one to carve a fake date into a turtle's shell is unclear. Perhaps some hoped to capitalize on the possession of such a "curiosity." If this were the case, the possibility that a photographer might have perpetuated (knowingly or not)—or even orchestrated such a hoax (i.e., an early, crude example of photographic manipulation), cannot be ruled out.

Surely we would have a better idea of whether this animal could have actually been marked in 1710 if its age could be inferred from the photograph at hand. Although *T. carolina* is a species said to have "negligible senescence" (Miller 2001), box turtles still show some age-related changes, and it is sometimes possible to approximate a turtle's age by examining certain physical characteristics (e.g., presence and number of scute annuli; see Dodd 2001). Turtles thought to be very old typically exhibit significant shell wear, in which cases growth rings can be less discernable or worn away completely. Elderly chelonians may also have depressed scutes resulting from calcium resorption. Despite the relatively poor resolution of the Tyson Brothers photograph, annuli are visible on the carapace of the turtle pictured, and the animal's scutes do not appear sunken. Although these findings may be interpreted as an indication that this turtle was not of exceptional age at the time it was photographed, it is important to note that shell wear and morphology are influenced by many factors (environmental and physiological), and there may be considerable variation among populations and individuals in terms of how age-related changes manifest. Consequently, this photograph alone does not allow for any reasonable estimate of this turtle's age (C. K. Dodd, Jr., pers. comm.).[3]

Alas, it seems that for the time being, the identity of this chelonian Civil War veteran remains a mystery. Nonetheless, this is perhaps the earliest photograph of one of America's most charismatic, beloved, and currently imperiled reptile species, and is of great historical value.[4] Rarely does an item surface with

[3] In instances where a turtle is found with a name or date carved on its shell, a close examination of the inscription can also potentially provide clues as to when the engraving was made, the type of tool that was used, and whether the turtle had reached maturity at the time it was marked (C. Kenneth Dodd, Jr., pers. comm.). Such an examination was obviously not possible in this case.

[4] The earliest known Anglo-American depiction of a box turtle is a watercolor painting by John White, ca. 1585 (Franklin and Killpack 2009; see Smith et al. [1990] for a history of White's illustrations).

the ability to captivate the minds of herpetophiles, Civil War aficionados, and antiquarians alike. In all likelihood, we will never learn what inspired the Tyson brothers, in the wake of the most notorious battle of the Civil War, to deviate from their standard battlefield views and portrait photography to document this animal—but the mystique makes this photograph all the more compelling.

Acknowledgments.—I thank Ken Dodd for his examination and analysis of the image discussed here. Useful reference material was provided by Kraig Adler. Bill Frassanito dated the photograph, and his extensive knowledge of the Tyson brothers was invaluable in the composition of this piece. Carolyn Davis, Carolyn Sautter, John Richter, Tim Smith, and Sue Boardman generously reviewed archives, offered helpful suggestions as to the possible origin of the photograph, and generally helped guide my research in the right directions.

Successful Incubation of Common Chuckwalla (*Sauromalus ater*) Eggs at the Bronx Zoo Using Suspended Incubation Method

The Common Chuckwalla (*Sauromalus ater*) is a desert-dwelling iguanid native to the southwestern United States and parts of Mexico (Shaw 1945). Reproduction of wild *Sauromalus* has been only partially described. Egg deposition often coincides with seasonal rain in spring and early summer (Abts 1988; Johnson 1965). Individual females become reproductively mature at approximately 2 years of age and an average snout–vent length (SVL) of 125 mm, experience oocytogenesis yearly, and have a mean clutch size of 6.9 eggs (Abts 1987, 1988).

Montanucci (1997) documented captive *Sauromalus* breeding. Timing of oviposition in captive and wild chuckwallas is consistent, with eggs being deposited between 28 April and 21 June. Montanucci (1997) also summarized incubation temperature and duration of eggs in media. Incubation periods ranged from74–112 days at temperatures between 28–35°C, with shorter incubation at higher temperatures (Fig. 2). Using standard egg incubation, whereby eggs were partially buried in fine sand, Montanucci (1997) reported low survivorship, with only one egg in a clutch of seven hatching at 30°C. This single hatchling exhibited neurological defects, leading Montanucci (1997) to conclude the animal had experienced oxygen deprivation.

Suspended incubation has previously been employed in herpetoculture (Köhler 2005). In this technique, eggs do not directly contact the media, and thus are not subject to suffocation by elimination of air spaces around the egg due to substrate compaction (Douglas 1993). Suspended incubation also eliminates the risk of embryos "drowning" if incubation media is too wet. Squamata Concepts® (Squamata Concepts LLC, Staten Island, New York, http://www.squamataconcepts.com/) has recently introduced the Suspended Incubation Method (S.I.M.) container as a standard tool for this method. Additionally, there are claims that the use of the S.I.M. container results in shorter incubation periods, fully absorbed yolk sacs, and potentially larger hatchlings (J. Andragna, Jr. pers. comm.).

The Bronx Zoo Department of Herpetology successfully hatched 23 *S. ater* from a total of 24 eggs in three clutches in 2010 and 2011. Herein we document the successful incubation of these eggs using suspended incubation in S.I.M containers. We also report egg and hatchling morphometrics.

Incubation.—Clutch size, date and incubation temperatures are summarized in Table 1. Clutch 1 consisted of nine eggs and was removed from the exhibit for incubation on 14 July 2010. Clutch 2, consisting of eight eggs, was removed from the exhibit on 24 May 2011. Clutch 3 contained seven eggs and was removed from the exhibit on 26 June 2011. Clutches 1 and 2 were removed from the exhibit within 24 h after oviposition. Clutch 3 took slightly longer to find, but was removed no later than 48 h after oviposition. Upon removal, all eggs were numbered, weighed, and measured. Egg mass, lengths, and widths are reported in Table 2.

All eggs were placed in a S.I.M. container (Fig. 1) and incubated over super-saturated vermiculite in a Thermo Forma (Model #3940) incubator. Although we could have incubated the eggs directly over water, we utilized vermiculate to prevent splash hitting the eggs during maintenance. However, standing water was visible in the bottom of the container. Clutch 1 was incubated at 31.5°C and 85% humidity. Clutch 2 was maintained at 31°C and 85% humidity for the first 12 days of incubation, at which point parameters were lowered to 30°C and 70% humidity because of requirements of another species placed in the incubator on that date. Clutch 3 was incubated at 30°C and 70% humidity for the entirety of incubation. The % humidity refers to settings of the incubator; the S.I.M. containers maintained an internal humidity close to 100% for the entirety of incubation (Fig. 3). All S.I.M. containers were aired weekly by removing the top for 1–10 seconds. Without removing eggs from the container, candling was occasionally performed while containers were open to document the progression of embryo development. Embryo development was noted as early as six days after oviposition. An Onset HOBO® data logger (Model # U10-003) was placed in the S.I.M. container with Clutch 2 to record temperature and humidity within the container.

As incubation progressed, remarkable size differences began to occur among eggs within each clutch (Fig. 1). Several eggs in

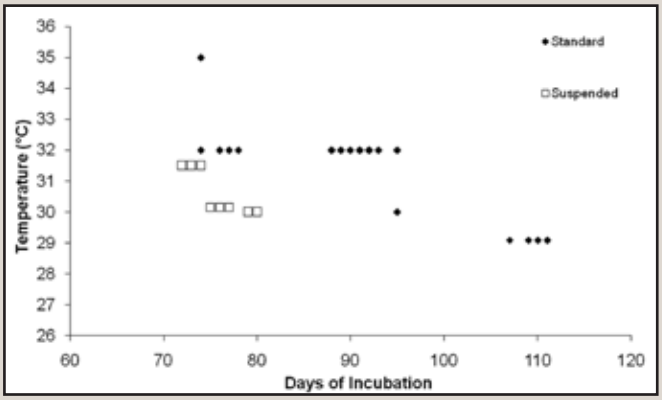

FIG. 2. Common Chuckwalla (*Sauromalus ater*) egg incubation period plotted against temperature for the Suspended Incubation Method (employed in this study) and data presented by Montanucci (1997) using the standard technique of incubating eggs directly in the media.

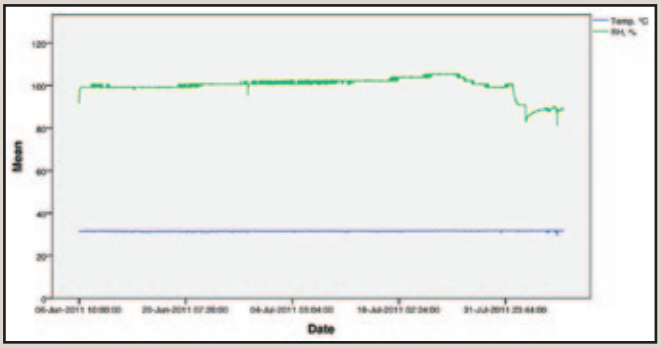

FIG. 3. Data obtained from an Onset HOBO® data logger (Model #U10-003) showing temperature and humidity inside S.I.M. container holding Common Chuckwalla (*Sauromalus ater*) eggs from clutch 2 (laid by female #2 on 24 May 2011) throughout the entire incubation period.

TABLE 1. Clutch size, collection date, temperature, and length of incubation for three clutches of Common Chuckwalla (*Sauromalus ater*) eggs.

Clutch #	# Eggs	Date collected	Incubation temp (°C)	Time to hatch (days)
1	9	14 July 2010	31.5	72–74
2	8	24 May 2011	31/30*	75–77
3	7	26 June 2011	30	79–80

*Clutch 2 was maintained at 31°C and 85% humidity for the first 12 days of incubation, at which point parameters were lowered to 30°C and 70% humidity because of requirements of another species placed in the incubator on that date.

TABLE 2. Mean (± 1 Standard Error) mass, length, and width of Common Chuckwalla (*Sauromalus ater*) eggs at time of oviposition. Clutch 1 (N = 9) laid by Female #1 on 14 July 2010; Clutch 2 (N = 8) laid by Female #2 on 24 May 2011; Clutch 3 (N = 7) laid by Female #1 on 26 June 2011.

	Clutch 1	Clutch 2	Clutch 3
Mean mass (g)	7.29 (± 0.138)	9.81 (± 0.188)	8.13 (± 0.078)
Mean length (mm)	34.67 (± 0.347)	37.63 (± 0.653)	34.69 (± 0.382)
Mean width (mm)	20.41 (± 0.151)	21.13 (± 0.295)	20.9 (± 0.282)

TABLE 3. Mean (± 1 Standard Error) mass, snout–vent length (SVL), and total length (TL) of Common Chuckwallas (*Sauromalus ater*) at time of hatching.

	Clutch 1	Clutch 2	Clutch 3
Mean mass (g)	5.27 (± 0.141)	8.49 (± 0.108)	7.03 (± 0.085)
Mean SVL (mm)	52.34 (± 0.694)	58.66 (± 1.056)	54.90 (± 0.675)
Mean TL (mm)	103.43 (± 1.157)	115.07 (± 1.202)	108.45 (± 1.057)

all three clutches grew so large as to necessitate pulling them upward and balancing them on top of the spacer rods to relieve pressure as they outgrew their allotted space within the S.I.M. container (Fig. 1). During the last 7–10 days of incubation, large amounts of condensation began forming inside the containers. We began opening the containers daily to wipe water droplets from the lid of the container to prevent these from raining down on the eggs. A drop in ambient humidity is seen on the data logger at this time (Fig. 3), which might be caused by the frequent opening of the containers during these last several days. Only one egg was lost during incubation; despite showing clear signs of fertility and early development, one egg from Clutch 2 sunk in and became moldy, necessitating its removal after 27 days of incubation.

Eggs in Clutch 1 began hatching on 24 September 2010 with the final hatchling emerging on 26 September, equating to an incubation period of 72–74 days. Clutches 2 and 3, incubating at a lower temperature, took longer to hatch. Clutch 2 began hatching 7 August 2011 taking 75–77 days and Clutch 3 hatched in 79–80 days beginning 13 September 2011 (Table 1). The minor difference in incubation times between clutches 2 and 3 was likely due to the difference in temperature at the beginning of incubation.

Hatchling morphometrics.—Mass, snout–vent length, and total length of all animals were recorded at the time of hatching (Table 3). All 23 chuckwallas lost weight in the first several weeks after hatching but a drop in weight after hatching is consistent with results for *S. hispidus* (Carl and Jones 1979). Our chuckwallas were observed eating as soon as five days after hatching; however, weight loss continued and animals did not rebound to birth weight until five to six weeks after hatching.

Discussion.—Suspended incubation is a common phenomenon in wild gekkonids (Henle 1990; Krysko et al. 2003) and has been reported in a wild colubrid snake by Kovac et al. (1995). In captivity, similar systems have generally been constructed using readily available materials, likely creating varying conditions that are difficult to replicate. The Squamata Concepts S.I.M. container is a valuable tool for herpetoculture, allowing suspended incubation data to be consolidated and easily replicated. We have utilized this tool to successfully incubate the eggs of various species, but prior to until now the use of this product has not been reported for many lizard species, including Common Chuckwallas (J. Adragna, Jr., pers. comm.).

Incubation of chuckwalla eggs using the suspended incubation method here was faster than expected based on data reported by Montanucci (1997). This observation potentially supports the claim that S.I.M. containers reduce incubation time (Fig. 2), although controlled studies would be needed to confirm this. Squamata Concepts also claims that hatchlings from eggs incubated in S.I.M. containers hatch without external yolk sacs. Our results support this claim as all 23 chuckwallas hatched at the Bronx Zoo had small umbilici at time of hatching, and all had fully absorbed yolk sacs.

Additionally, it has been shown that variations in moisture of incubation media might significantly affect the physical characteristics of hatchling lizards, with wetter media resulting in larger hatchlings (Overall 1994; Phillips et al. 1990; Phillips and Packard 1994). Alternately, Overall (1994) found that hatchling *Sceloporus merriami* incubated in very wet media grew slower than those hatched from drier media, particularly in later months. Although eggs in S.I.M. containers have no contact with media, they are exposed to an ambient humidity close to 100% (Fig. 3). We have included hatchling morphometrics (Table 3) to allow for future comparisons between these measures in chuckwallas hatched using suspended incubation and other incubation techniques.

Acknowledgments.—We thank the Bronx Zoo Department of Herpetology for assistance. We also thank Pat Thomas and Don Boyer for reviewing a previous version of this manuscript. We greatly appreciate all assistance and communication from John Andragna Jr. and Gregg M. Madden of Squamata Concepts LLC.

Captive Propagation of the Southern Dwarf Siren (*Pseudobranchus axanthus*)

Southern Dwarf Sirens, *Pseudobranchus axanthus* (Netting and Goin 1942) are small, fully aquatic, freshwater salamanders with external gills and a slender eel-like body (Conant and Collins 1991). Two subspecies are recognized, *P. a. axanthus* and *P. a. belli*, both endemic to peninsular Florida, USA. Currently, *P. axanthus* is listed by IUCN as a species of Least Concern (LC); however, the southern populations of *belli* are thought to have declined due to historic and ongoing habitat alteration including drainage of surface waters associated with development (Moler and Kezer 1993; Petranka 1998). Little is known about life history and reproduction of *P. axanthus*. There have only been two other successful captive breedings of *Pseudobranchus* to date: *P. striatus* (Pfaff and Vause 2002) and *P. axanthus* (Kowalski 2004).

Captive husbandry.—In September 2009, K. L. Krysko (FLMNH) donated nine (mixed gender) wild-caught adult *P. a. axanthus* from Alachua County, Florida, to the Central Florida Zoo & Botanical Gardens. The specimens were split into two groups of five and four individuals. Initially, they were housed indoors in 38-liter glass aquaria (30 cm depth; pH 7.0 ± 0.1) with sand substrate (12.9 cm depth), and leaf litter. No artificial lighting was offered, although tanks were set near windows to provide ambient lighting and a natural photoperiod. Specimens were fed a rotation of live tubifex worms (*Tubifex tubifex*), HBH brand Newt & Salamander Bites, Tetra brand spirulina flakes, and San Francisco Bay brand frozen brine shrimp three times per week. Small native snails were offered occasionally, but consumption was never observed. The preferred food item appeared to be tubifex worms. The Dwarf Sirens would burrow into the sand substrate with only their heads exposed. They would grab food items that landed near their heads. On many occasions, Dwarf Sirens were observed nosing food items around the enclosure before consuming them. No reproductive behaviors were observed during this initial period.

In April 2010, Tuff Stuff Product rubber cattle troughs measuring 152 cm (length) × 91 cm (width) × 61 cm (height) were established outdoors (Fig. 1). Initial water depth was set at 15.2 cm (90% tap water, 10% pond water). Rainwater was allowed to accumulate in the troughs until the water depth reached 30.48 cm above the bottom substrate. The bottom was covered with 2.54 cm of sand with a covering of leaf detritus 0.51 cm thick. Initial water temperature was 27.8°C. Various species of aquatic plants including Parrot Feather (*Myriophyllum aquaticum*), Alligator Weed (*Alternanthera philoxeroides*), and Spatterdock (*Nuphar luteum*) were added from a local stream (Fig. 2). The troughs were placed in a pen enclosed with 2.5 cm × 1.3 cm coated wire located in shaded ambient sunlight that received some direct sunlight in the morning. The troughs were set up early May 2010 and allowed to accumulate both terrestrial and aquatic locally

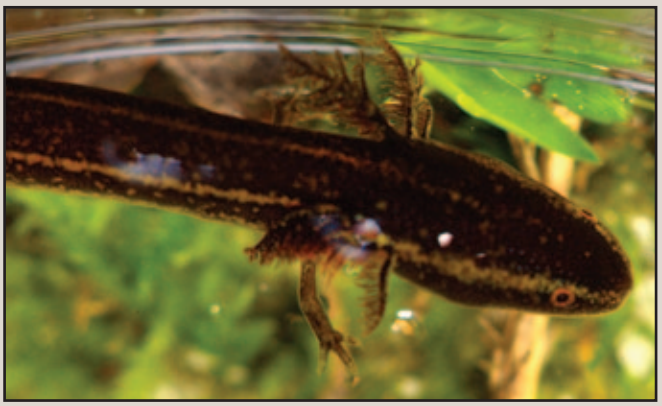

FIG. 3. Lateral view of the head of a *Pseudobranchus axanthus* larva.

occurring invertebrates for two weeks. *Pseudobranchus* are not sexually dimorphic, although female *P. axanthus* are generally more robust than the males (P. E. Moler, pers. comm., 2010). What were presumed to be two male and two female *P. axanthus* were added to the outdoor enclosure on 16 May 2010. They were fed frozen blood worms and brine shrimp as a supplement to the established invertebrates once a week. The sirens were expected to feed primarily on the aquatic invertebrates that had colonized the enclosure, predominately mosquito larvae (family Culicidae). Water in the outdoor tank had a pH of 7.8–8.0 during May and early June. By late June the pH had decreased to 7.2 ± 0.1. By December it had further decreased and remained at 6.5 ± 0.2. Water changes were not routinely performed during this experiment; however, rainwater was collected and added to the tank when needed. Water temperature never exceeded 32.2°C during the summer months and never went below 21.1°C in the coolest winter months.

Little is known about the method of reproduction for *P. axanthus*, but the oviposition period is thought to be November through March (Petranka 1998). A similar species, *P. striatus*, found from southern South Carolina, Georgia, and northern Florida (Liu et al. 2004) has a documented oviposition period of mid June through August in captivity (Pfaff and Vause 2002).

In the present study, single *P. axanthus* eggs (5) were first found on low roots and decaying leaves in late December 2010, within 18 cm of each other. The first larvae were observed on 4 February 2011. The jelly envelopes of the eggs could still be seen attached to leaf detritus and roots after larvae hatched. Egg incubation required 4–6 weeks. No mortality of hatchlings was observed; however, assessing an accurate count of eggs and offspring proved to be difficult due to the dense leaf detritus used as substrate. Twelve larvae were removed from the enclosure when seen during February and March 2011 (Fig. 3). At this time, larvae measured a mean total length of 2.73 cm (N = 12; 2.03–3.56 cm). After measurement, larvae were placed back into the original enclosure and fed the same diet rotation as described above. Adults were removed from the enclosure to prevent cannibalism of the larvae. After six months (September 2011) the tub was drained and the larvae were measured again. All 12 original larvae had more than doubled in size, measuring a mean total length of 6.41 cm (N = 12; 4.82–7.45 cm) and a mean mass of 0.31 g (N = 12; 0.22–0.48 g). In November 2011, all 12 larvae were thriving in the outdoor enclosures in nearly identical conditions as the adults. No further evidence of reproduction has been observed.

*Acknowledgments.*I thank Nick Clark, Charles Becker, and Ariel Horner with the CFZ&BG Department of Herpetology. I have much gratitude towards Scott Pfaff (Riverbanks Zoo), and Paul E. Moler and Bill Turner (Florida Fish and Wildlife Conservation Commission) for their guidance and critical comments on this note. I also thank Kenneth L. Krysko, Florida Museum of Natural History, for supplying the specimens used during this study.

Observations on the Captive Maintenance and Reproduction of the Cascade Glass Frog, *Sachatamia albomaculata* (Taylor, 1949)

The Cascade Glass Frog, *Sachatamia albomaculata* (Centrolenidae), has a wide distribution from north-central Honduras to western Colombia and northwestern Ecuador (Savage 2002; Solis et al. 2010). This species has been observed from sea level to 1500 m in elevation where it is typically found along streams in humid lowland and premontane forests with little or no alteration, although it has also been found in more degraded habitats (Kubicki 2007). The International Union for the Conservation of Nature (IUCN) lists *S. albomaculata* as Least Concern with a stable population trend (Solis et al. 2010).

Herein we report the methods utilized for successful maintenance and reproduction of *Sachatamia albomaculata* at the Atlanta Botanical Garden (ABG) and Zoo Atlanta (ZA) in Atlanta, Georgia, USA, and the Como Park Zoo and Conservatory (CPZC) in St. Paul, Minnesota, USA. Of the 146 species of centrolenids described to date (Frost 2011), 54 are listed by the IUCN as Vulnerable, Endangered, or Critically Endangered (IUCN Red List), with a number of these recommended for *ex situ* management programs by Amphibian Ark (www.amphibianark.org). believe the information presented here will be useful in future efforts to maintain *ex situ* populations of threatened species of Glass Frogs.

Specimen Acquisition and Husbandry Methods.—A group of *Sachatamia albomaculata* (Fig. 1) were collected from the region of El Valle de Antón, Provincia de Coclé, Panamá and brought to ABG and Zoo Atlanta (ZA) in 2005 (Gagliardo et al. 2008). Following importation, specimens were quarantined for a period of 30 days during which they were treated for amphibian chytrid fungus (*Batrachochytrium dendrobatidis*) as outlined in Pessier and Mendelson (2010). After this quarantine period, 3.1 specimens were transferred to ZA, 1.1.2 to CPZC, and 5.2 to ABG.

The 5.2 ABG specimens were moved to an enclosure measuring 60 × 30 × 90 cm furnished with live plants for cover and to provide sites for egg deposition. A "false-bottom" substrate made from plastic light diffuser wrapped in plastic coated screening was used to allow for rapid cleaning and improved hygiene. Light was provided by a single 55-watt compact fluorescent fixture with a cycle of 12 hours on and 12 hours off. Temperatures ranged from 18–28ºC. Humidity and moisture were maintained through use of an automated misting system. Food items were offered three times weekly and consisted largely of 3–5 mm crickets (*Acheta domestica*), flightless fruit flies (*Drosophila hydei*), and occasional offerings of Bean Weevils (*Callosobruchus maculatus*). All food items were supplemented with alternate dustings of Repcal D3® and finely powdered Men's Health® vitamins. In 2010, Repashy Superfoods® Calcium plus ICB was added to the supplement regime.

In 2008, ABG acquired and outfitted an insulated shipping container as an amphibian breeding facility (Fenolio et al. 2009) into which the remaining 3.1 Cascade Glass Frogs from ABG and 2.1 from Zoo Atlanta were moved. Once transferred to this facility they were split into groups of 1.1, 1.1, and 3.0 each into Zoo Med® terrariums measuring 30 × 30 × 45 cm and furnished as above (Fig. 2A). Humidity and moisture were regulated through the use of an automated misting system operating six times daily during a simulated wet season from November–April and two times daily during a simulated dry season from May–October. Individual misting events ranged from three to 10 minutes each with the shortest misting events taking place during the simulated dry season.

Adults of *S. albomaculata* at CPZC were housed in terrariums with dimensions of ~30 × 25 × 50 cm. Substrate consisted of a layer of hydroponic clay which was covered with a layer of moistened sphagnum moss. A water dish and live plants (*Epipremnum aureum*) were also included. Temperatures ranged from 18–26ºC. Enclosures were misted six times daily for periods ranging from 3–10 minutes. Lighting was provided with an individual 50 watt Eiko ® Supreme halogen spot light with the glass lens removed. A 12:12 daily light cycle was maintained. The diet consisted of fruit flies (*D. hydei*) and small crickets (*A. domestica*) offered three times weekly. Initially, food items were dusted with a mixture of Rep Cal® without D3 and Nekton-Rep®. Beginning in 2011, all food items were dusted with Repashy Superfoods® Calcium plus ICB.

Specimens at Zoo Atlanta were housed similarly to those at CPZC. However, lighting was provided with fluorescent lights as opposed to Eiko ® bulbs. Misting was by hand and conducted once or twice daily. The diet was composed of fruit flies (*D. hydei* and *D. melanogaster*) and small crickets (*A. domestica*). On occasion, house flies (*Musca domestica*) were offered. Following the loss of the lone female in this group, a single female was sent from ABG in late 2007. However, in 2008, all individuals from Zoo Atlanta were moved permanently to ABG.

Specimens of *S. albomaculata* proved to be relatively hardy captives given that their environmental needs were met. However, some health concerns were noted, including: a male specimen at CPZC with chronic intestinal prolapse, susceptibility

to heavy infestation by nematodes in the genus *Rhabdias*, and in the case of one female specimen housed at Zoo Atlanta, an infection of the eye that resulted in its removal (S. Rivera, pers. comm.). Despite what would seem a large handicap, this specimen was still alive at the time of submission (March 2012) and had produced a number of offspring after transfer back to ABG (RLH, pers. obs.).

Breeding.—Regular breeding events did not occur at ABG until late 2008, although a few egg masses were produced between 2005 and late 2008. Axillary amplexus was observed (Fig. 3). Pairs at ABG produced eggs in most months, although the largest number of eggs was deposited from January–May. This is consistent with wild observations in Panama in which egg masses were observed throughout the year. However, the largest number of egg masses and individual frogs in the field were observed in the months of November and December (Griffith pers. obs.).

The number of eggs per clutch varied from 28–56 at ABG with eggs numbering from 30–60 at CPZC. Clutches were typically deposited on the upper surface of a leaf in a single-layer cluster with an opening in the center as described by Kubicki (2007; Fig. 4). On several occasions at ABG eggs were laid directly on the glass sides of the enclosure, within the phytotelma of a bromeliad, or on the enclosure floor. No parental attendance was observed following oviposition at ABG. However, males at CPZC were observed to sit adjacent to eggs. Of further interest, in two instances, a male was observed sitting in the water dish for a period, and then moving through the enclosure toward the egg mass. Although deposition of water was not directly observed in either instance, the behavior implies that males may be transporting water to hydrate eggs. Further observations are necessary to confirm this behavior.

Handling of Eggs and Larvae.—Once discovered, eggs at ABG were typically removed from the adults' enclosure (typically on a leaf of *Calathea*) and placed in a covered plastic container with a small amount of water until hatching. Eggs deposited on the glass or enclosure floor were gently scraped from the surface using a razor blade and then placed on top of a cut leaf in a container as described above. Eggs began hatching roughly 2–3 weeks post-oviposition. Larvae were transferred to plastic containers measuring 25 × 15 × 10 cm that were filled to a depth of 7–8 cm with carbon-filtered tap water and a thin substrate of sand and pea gravel (Fig. 5). Larvae were raised communally in groups no larger than 30 per container. Temperatures were maintained at 20–25°C. Live Java Moss (*Vesicularia* sp.) and small amounts of Common Duckweed (*Lemna minor*) were included to provide additional cover. Water was changed at a rate of approximately 50% daily.

Larval diet consisted mainly of Sera Micron®, a commercially-produced Spirulina-based finely-powdered fish food. This was mixed with water to form a thick paste and spread onto microscope slides as described by Hill et al. (2011). This method has proven successful for larvae of multiple frog species, including two other centrolenids in the ABG collection: *Cochranella granulosa* and *Teratohyla spinosa*. As such, it was expected to work for *S. albomaculata*. However, larvae failed to thrive when food was offered in this manner and would typically expire within 30 days of hatching. Similar results were observed at Zoo Atlanta. Following several failed attempts, in early 2009, one of us (JBK) offered Sera Micron® mixed with finely ground HBH Frog Bites ® in paste form directly on the substrate of the rearing containers (Fig. 6). Larval survival increased upon switching to this feeding strategy and the first metamorphosis occurred at ABG in March 2009 with additional successes following throughout 2009, 2010, and 2011.

FIG. 5. Container used for rearing larvae at ABG.

Larvae at CPZC were reared in glass aquariums measuring approximately 50 × 25 × 30 cm with water depth from 10–20 cm. Larval density did not exceed 30 per aquarium. Temperatures were maintained at 22–25°C with the use of aquarium heaters. Live plants, oak leaves, a small amount of sphagnum moss, and a layer of gravel were added. In addition, live snails were added to combat black algae growth. Partial water changes were conducted on a daily basis. At approximately eight months, water levels were lowered as larvae would appear stressed with deeper

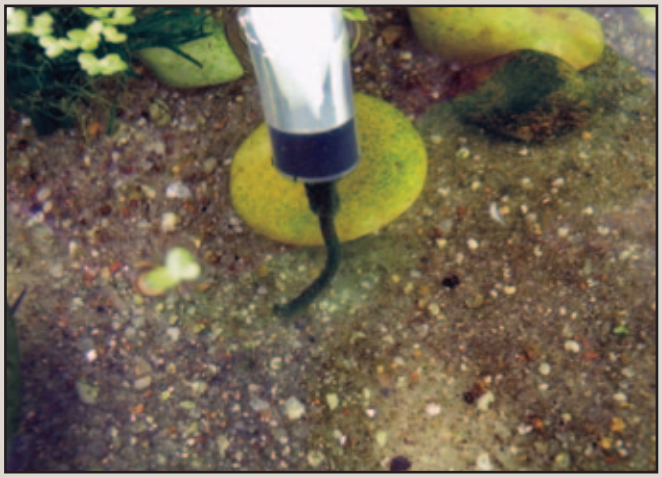

FIG. 6. Sera Micron ® and HBH Tadpole and Frog Bite ® mixture being injected onto larval enclosure substrate.

water at this stage of development. The diet consisted entirely of Sera Micron® on microscope slides. Why this method proved successful at CPZC but not at ABG or Zoo Atlanta is unknown.

Handling of Metamorphs and Juveniles.—At ABG, time from hatching to metamorphosis ranged from 12–40 weeks. Larvae from the same clutch metamorphosed at highly variable rates despite all being housed under similar conditions. The reason for this is unknown as manipulations using smaller numbers of larvae per rearing container still resulted in variable rates of metamorphosis within single cohorts. After emergence of all four limbs, newly metamorphosing individuals were moved into plastic quart-size deli cups with vented lids, roughly 1 cm of filtered water, and a small mound of moistened sphagnum moss as a haul out area. Each metamorph was housed separately and additional moss was added to prevent drowning once it started spending large amounts of time out of the water (typically within 3–5 days after front limb eruption). They began feeding on small flightless fruitflies (*D. melanogaster*) after full absorption of the tail, which took from 7–20 days, although some specimens were observed to feed before full tail absorption. As they grew, food item size was increased to match that of the adults. They were hand misted once daily and temperatures were maintained as for adults. Individuals were raised in this manner for 5–8 months to ensure easy access to food items and provide easy monitoring, then moved into larger enclosures as deemed necessary.

When rear limbs were well developed and dorsal patterning appeared, late-stage larvae at CPZC were moved into an enclosure measuring 50 x 25 x 30 fitted with a ramped polypropylene false bottom to serve as a haul out area. A vented lid was included to prevent escapes and partially covered with plastic wrap to maintain high humidity. The water portion was kept at a depth of approximately 7–8 cm and included furnishings similar to the larval enclosures. Partial water changes were conducted daily. Small plants and moistened sphagnum moss were added to the haul out area. This enclosure was misted twice daily. Sera Micron® slides were offered until metamorphs left the water, at which point they were offered springtails (*Collembola* sp.), fruit flies (*D. melanogaster*), and newly hatched crickets (*A. domestica*) daily. Once they doubled in size, young frogs were moved into Zoo Med® terraria as described above.

Conclusions.—*Sachatamia albomaculata* is currently listed by the IUCN Red List as a species of Least Concern and wild populations appear stable at this time (Solis et al 2010). However, it was postulated by Kubicki (2007) that *S. albomaculata* may contain multiple species. If this is proven to be the case, then the conservation status of this potentially cryptic species complex may change. Of the three currently recognized species of *Sachatamia* considered by the IUCN at the time of writing, one is listed as Vulnerable (*S. punctulata*). Another, *S. ilex*, which often is sympatric with *S. albomaculata*, has been listed as Least Concern. However, populations of *S. ilex* have experienced declines (Solis et al. 2010). A group of *S. ilex* from the El Valle region of Panama was brought to Zoo Atlanta in 2005 where a handful of breeding events occurred. However, as with *S. albomaculata*, early rearing attempts proved unfruitful and unfortunately, the US breeding population expired before any further successes were gained. The methods described above could be applied to *ex situ* management plans for other glass frogs deemed in need, not just members of the genus *Sachatamia*.

Acknowledgments.—This manuscript is dedicated to our colleague and co-author Julia Beth Kaylock (1980–2009). Special thanks are extended to Ing. Lorenzo Hincapie (Hotel Campestre), Roberto Ibáñez, and the personnel and government of the Republic of Panama. Permits were granted by the Autoridad Nacional del Ambiente (ANAM, permit SEX/A-81-05). Acknowledgments also go to Ron Gagliardo and Joseph R. Mendelson III, for editorial assistance as well as to Danté Fenolio and Mark Mandica for husbandry assistance. Further gratitude goes to George and Mary Rabb, Cynthia Jeness, and Bill and Claire Simmons for their support of *ex situ* amphibian conservation efforts.

Growth Rates of Neonate Red Cornsnakes, *Pantherophis guttatus* (Colubridae), When Fed in Mutually Exclusive Mass-Ratio Feeding Categories

Studies on growth rates of snakes have long been investigated (Barnard et al. 1979; Carpenter 1952; Ford 1974; Kauffeld 1943) and are still ongoing (Boback 2003; Hill and Beaupre 2008; Madsen and Shine 2001). There are two growth measurements that are generally recorded when measuring snakes: length and mass (Charland and Gregory 1989; Franz 1977; Kauffeld 1943; Myer and Kowell 1973). A third and easily acquired measurement is girth at mid-body but this is rarely reported. Straight-line length is occasionally used but the most commonly reported length measurement is snout to vent length (SVL; Seigel and Ford 1988). It is important to state which measurement technique is being used (Fowler and Salamao 1995).

In a study on *Nerodia sipedon*, Brown and Weatherhead (1999) reported two variables that are likely to affect snake growth rates: energy intake and climate. Laboratory investigations allow for control of both of these variables. Many studies hold temperature constant and investigate feeding regimes (Barnard et al. 1979; Dmi'el 1967; Ford and Seigel 1994). Myer and Kowell (1973) showed that frequency of feeding and food mass can affect growth in *Thamnophis sirtalis*. As a snake consumes more food its total body mass usually increases but this phenomenon may not accurately relate the size (mass) of a snake to its age because body mass can be impacted by multiple variables. Snake mass has been shown to fluctuate with feeding regimes (Myer and Kowell 1973) and varying reproductive efforts (Charland and Gregory 1989). Neonate *Pantherophis guttatus* have been shown to convert up to one-third of their food weight into added body mass (Love and Love 2005). However, age can be predicted based upon SVL if the sampling period of the growth model is large enough and the specimen collected is in close regional proximity to the growth model sample (Brown and Weatherhead 1999). Individual marine iguanas total length has been shown to shrink during times of low food availability (Wikelski and Thom 2000) but this growth reduction phenomenon has not been shown in snakes (Madsen and Shine 2001).

In an early field growth study, Kaufman and Gibbons (1975) evaluated the relationship of SVL and mass of thirteen species of snakes that were primarily road collected and reported a correlation coefficient between SVL and mass of ≤0.82 with *P. guttatus* being 0.97. Barnard et al. (1979) investigated the growth rates of ten sibling *P. guttatus* for ca. 2 years in a laboratory setting. Snakes were fed weekly meals of mice and were measured (total length and mass) monthly. A correlation coefficient of 0.978 was reported between total length and mass. They found that growth is more dependent on food consumed rather than age, length is logarithmically related to body weight, and weight gain and length are related to the amount of food ingested.

Many investigators have evaluated snake growth at different feeding frequencies (Dmi'el 1967; Wharton 1966) but to our knowledge, none have evaluated snake growth when fed in a mass-ratio feeding category with a constant frequency. A mass-ratio (MR) feeding category is a mutually exclusive feeding category calculated as the percent of prey mass to snake mass (Mehta 2003). The objective of this study is to evaluate the growth (length, girth, mass, and shedding rates) of neonate *P. guttatus* when fed in mutually exclusive MR feeding categories. We collected data on the growth rates and shedding frequencies of captive *P. guttatus*.

Materials and Methods.—The 18 hatchling snakes used in this study came from the personal collection of David Penning. Parents of the offspring were originally obtained from Miles of Exotics in Kansas City, Missouri. All snakes shared the same father and came from one of two mothers. All hatchlings displayed phenotypically normal traits but carried various non-expressed alleles that their mothers displayed but they did not. The first clutch of snakes began hatching on 8 June 2010 and all snakes hatched by 15 June 2010. All snake eggs were incubated in the same type of incubator (Little Giant® Still Air Incubator) with the same average temperature (28°C) and humidity (≤80%).

Each neonate was held individually in a cage internally measuring 27.9 × 27.9 × 15.2 cm. A sliding, clear piece of glass was used for the lid. Multiple 5-mm holes were drilled into the backs and fronts of the cages for proper air exchange. This allowed proper ventilation without exposing each snakes to the visual cues of the other snakes. Ambient room temperature averaged 27.9°C. Each cage was spot cleaned daily and bedding was changed *pro re nata*. No mites or parasites of any kind were observed during the experiment. Water was available at all times.

Hatchlings were then checked once per week for their first shed. The feeding trials began the following scheduled feeding day upon the discovery of each snake's first shed. The order in which the snakes were placed into each category was determined by a random number generator. House Mice (*Mus musculus*) were the only food given to snakes in the experiment. Each snake was put into a feeding schedule of one meal per week. The two feeding categories were labeled as small and large. The small feeding category had a prey mass-ratio of 20–40% of the snake's mass while the large category had a ratio of 41–60% of the snake's mass. The original categories followed the format of Mehta (2003) but hatchlings were born at a small size (mean = 4.4 ± 0.68 g) that prohibited the narrower ranges. Snakes were weighed using an AWS high capacity precision pocket scale (0.1 g) the day prior to each feeding trial and prey mass range was calculated for them. A prey item within the snake's range was chosen ca. one hour before trials began. Mice were transported to the university in containers in which all individuals of similar mass were grouped together. Mice were then chosen at random and weighed to match the appropriate snake. Snakes that failed

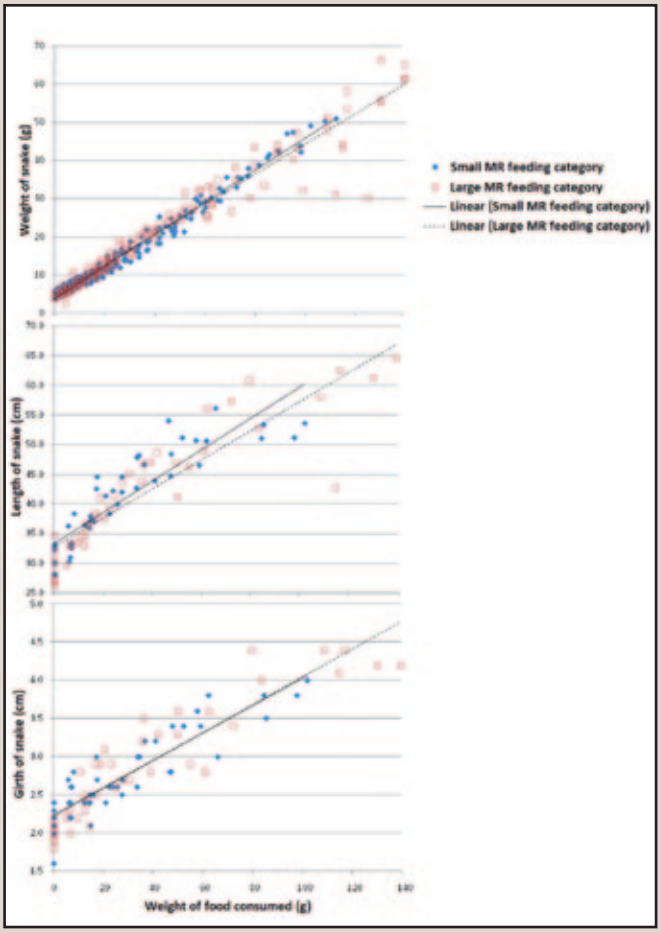

FIG. 1. Rate of growth increase for weight (A), length (B), and girth (C) based upon the growth rates of 18 individual Red Cornsnakes (*Pantherophis guttatus*) in two feeding categories over a 22-week feeding trial.

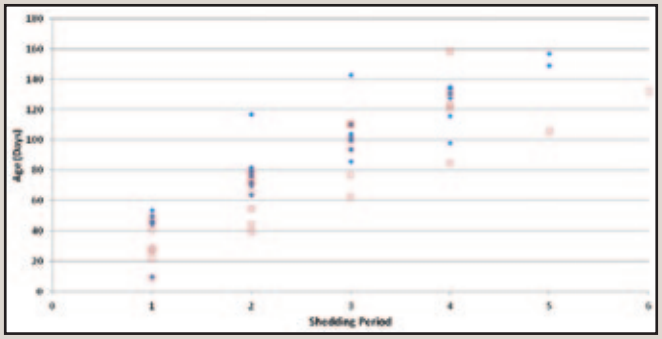

FIG. 2. Age of snakes at sequential shedding periods for both MR feeding categories. Blue fill indicates the small MR feeding category, red outline indicates the large MR feeding category.

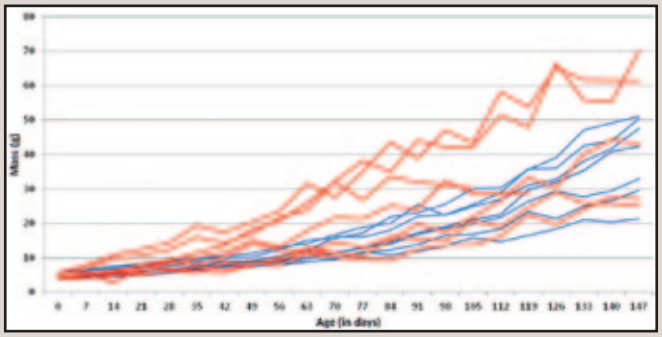

FIG. 3. Relationship between weight (mass) of individual snakes and age (in days). Blue lines represent snakes in the small MR feeding category and red lines represent snakes in the large MR feeding category.

to eat for four weeks in a row were removed from the study. A failed feeding trial was considered a period of 40 minutes at any point of the feeding trial in which the snake did not engage the prey.

Although previous studies measured snake length using snout to vent length (Fowler and Salamao 1995), we used snout to tail length for two reasons: the measurement data attained from this study came from a larger project requiring minimal handling; and to compare our data to that of Barnard et al. (1979). Because of this, snakes were digitally and not manually measured. Snakes were placed on a piece of 0.5 cm graph paper and photographed directly overhead approximately 100 cm above the snake. Pictures were then entered into the SnakeMeasurer© program to get total length. This allowed for the snake to orient its body in a natural position without being manually manipulated. Snake length was recorded to the 0.1 cm. Girth (in cm) was measured using a flexible measuring tape and wrapped around the snake at midbody and measured to 0.1 cm. Shedding events were recorded *pro re nata*. All statistical analysis was conducted on Minitab 14.

Results.—Snake mass is significantly related to the amount of food consumed in the small and large MR feeding categories ($P < 0.05$, small $r^2 = 0.974$, large $r^2 = 0.949$) and expressed by the following simple linear regression models: Small snake mass = 3.85 + 0.419 (total food consumed), Large snake mass = 4.84 + 0.395 (total food consumed). The intercepts and slopes of the two regression models are not significantly different (General Linear Model, $P > 0.05$).

Snake length is significantly related to the amount of food consumed in the small and large MR feeding categories ($P < 0.05$, small $r^2 = 0.795$, large $r^2 = 0.810$) and expressed by the following simple linear regression models: Small snake length = 33.3 + 0.263 (total food consumed), Large snake length = 32.7 + 0.244 (total food consumed). The intercepts and slopes of the regression models are not significantly different (General Linear Model, $P > 0.05$).

Snake girth is significantly related to the amount of food consumed in the small and large MR feeding categories ($P < 0.05$, small $r^2 = 0.807$, large $r^2 = 0.839$) and expressed by the following simple linear regression models: Small snake girth = 2.23 + 0.0180 (total food consumed), Large snake girth = 2.21 + 0.0183 (total food consumed). The intercepts and slopes of the regression models are not significantly different (General Linear Model, $P > 0.05$). Regression models can be seen in Fig. 1.

Correlations were run among all three growth forms. All correlations are significant at $P < 0.05$. Mass and girth Pearson correlation coefficients are 0.912 for the small MR category and 0.934 for the large MR category. Mass and length Pearson correlation coefficients are 0.881 for the small MR category and 0.889 for the large MR category. Girth and length Pearson correlation coefficients are 0.853 for the small MR category and 0.922 for the large MR category.

Snake shed cycles from this experiment are presented in the same format as that of Myer and Kowell (1973) in Fig. 2.

Discussion.—In both the small and large MR feeding categories, growth in mass, length, and girth was significantly related to total food consumed. There was no significant difference

between the regression slopes of the small and large MR feeding categories for all three growth forms. This statistically supports the concept that food ingested (regardless of how it is ingested) will result in similar growth. Snakes in the larger MR category attained a larger mass, girth, and length by the end of the feeding trials but the overall growth models were not significantly different. It took the snakes in the small MR category longer to attain similar size in all growth forms but arrived at similar sizes as the large MR category per total food consumed. Mass, length, and girth gained by the snakes in this study depended upon the total amount of prey ingested. This supports the idea that snake mass is not dependent upon age alone. These findings agree with Barnard et al. (1979) in that snake mass is not an accurate estimation of snake age. These findings also support Barnard et al. (1979) in that variation (in mass) among individuals increased as amount of food increased and is presented in a similar format in Fig. 3. Snake size (mass) should not be used as an estimator of age beyond reproductive status (which generally accompanies a minimum age bracket).

We report a similar correlation coefficient as Barnard et al. (1979) between snake length and body weight (mass) in *P. guttatus*. A longer study is needed to specifically examine the growth associations in mutually exclusive MR feeding categories as Barnard et al. (1979) was a much longer study than the 22-week length of this experiment. In both the small and large MR feeding categories the correlation coefficients were similar for mass and length, mass and girth, and length and girth. These correlation coefficients suggest that there is a close association between the two MR feeding categories growth forms. Length, girth, and mass all covary with one another in a similar manner.

Cornsnakes had a variable % mass gain [(current pre-feeding snake mass – previous pre-feeding snake mass) / (prey mass from previous week)*100] in body weight per feeding event. Love and Love (2005) stated that neonate *P. guttatus* can convert up to 33% of their food (prey) weight into body mass. Snakes in this study had a percent mass gain range of -15% to 93% mass gain per feeding event. The average percent gain for the small MR feeding category was 40 ± 19.3%. The average percent gain for the large MR feeding category was 45 ± 22.4%. The averages suggest that it is more advantageous to eat larger prey (if the goal is mass gained) but when accompanied by the standard deviations there is no discernible difference between the percent mass gains of the two MR feeding categories. This observation is a much more variable number than the percentage presented by Love and Love (2005). There may be varying metabolic factors impacting mass gain that were not addressed in this study. A mass gain ratio does not appear to be a reliable measure of energetic (body mass) gain.

Acknowledgments.—We thank the Department of Biology and Earth Science's faculty, staff, and graduate students, more specifically S. Wilson, K. Dean, and J. Mittelhauser. We also thank A. Brass, M. Perkins, and A. Bossert for their guidance and editorial reviews. This research was conducted under IACUC protocol #10-3212.

HERPETOCULTURE NOTES

TESTUDINES — TURTLES & TORTOISES

***PYXIS ARACHNOIDES ARACHNOIDES* (Spider Tortoise). DRINKING BEHAVIOR.** Animals from arid or seasonally dry habitats often have unique adaptations for capturing water from rare or unpredictable rainfall events (Costa 1995. Behavioural Adaptations of Desert Animals. Springer-Verlag, Berlin. 198 pp.). Water-capture behaviors have been described for certain arid-land tortoises of the genera *Psammobates* and *Kinixys*, which involved elevating the rear part of the carapace by extending the hind legs while splaying the forelimbs forward, allowing water to flow down the "gutter" formed from the flared marginal scutes and along the forelimbs to the mouth (Auffenberg 1963. Anim. Behav. 11:72–73).

I observed a very different drinking posture and behavior in 137 wild-caught, confiscated *Pyxis a. arachnoides* in Madagascar. The tortoises were being temporarily housed in Antananarivo after the confiscation of an illicit smuggling attempt, apparently to get them out of the country. Their general health was to be monitored before being transported to a facility nearer to their native range in preparation for repatriation. When being rehydrated via pipette from overhead to simulate rainfall, the tortoises assumed an unusual posture. Once contacted by water droplets, tortoises went from fully withdrawn into the shell to having limbs extended and head fully extended upward. Front limbs were extended downward while rear limbs were splayed and slightly bent so that the tortoise's anterior was higher than the posterior. Head and neck were extended upward or backwards over the carapace, and the tortoise would take in the water through both nares and mouth; swallowing was presumed due to visible gular undulation. Each tortoise pipetted assumed this posture, and several held it for more than 30 minutes, regardless of continued pipetting. A similar posture has been observed in another, closely-related Malagasy tortoise species (*Astrochelys radiata* [Radiated Tortoise]) during actual and simulated rainfall (pers. obs.), however it has not been linked to drinking. This is apparently the first report of this unique water gathering and drinking behavior in *Pyxis*, a critically endangered taxon (IUCN 2011. IUCN Red List of Threatened Species. Version 2011.2. <www.iucnredlist.org>).

I thank Edward E. Louis of the Madagascar Biodiversity Partnership, the Turtle Survival Alliance, and the Turtle Conservation Fund for funding and facilitating my chelonian research in Madagascar, and Ryan C. J. Walker for his assistance and support. I also thank James H. Harding for careful review and edits.

***STIGMOCHELYS PARDALIS* (Leopard Tortoise). BEHAVIOR.** These observations involve a pair of captive-bred adult *Stigmochelys pardalis* that live in an enclosed garden near the Gulf of Thailand (where is the Gulf of Thailandin the Hup Kapong subdistrict, Cha Am, Petchaburi Province, Thailand (12.760642°N, 99.912908°E). This pair has produced several clutches of hatchlings. The hatchlings are allowed to graze during the day in screen-protected pens while the adults are left free to roam in the enclosed garden. Normally therefore there is no contact between adults and juveniles.

Under a full moon on New Year's Eve 2011 the female was observed to lay eggs in a protected hilly area of the garden. One morning after a night of heavy rain, four hatchlings were found in the garden, approximately five months after oviposition. At about one week of age, the hatchlings were placed close to the mother and father. There were clearly audible vocalizations from the mother, directed toward the juveniles, and also from the juveniles to the mother. The calls were repeated low-pitched "cooing" sounds whose pitch rose and then fell and lasted between 1–2 seconds. Vocalizations began within a minute of the hatchlings being placed closed to the mother and continued for about 5 min. For the next several hours, the four hatchlings and the mother walked together in close proximity in the garden, stopping often to graze. The mother appeared almost hyperactive and was clearly intensely interested in the juveniles. Two days later the juveniles were again placed close to the mother. Again, there were bi-directional vocalizations as previously described and the five animals moved as a group through the garden. On subsequent trials, however, no additional vocalizations were heard when the juveniles were placed close to the mother, although occasionally one or two of the juveniles stayed close to the mother for several hours.

Acoustic vocalizations are well known between male and female *Stigmochelys pardalis* during courtship and mating. Vocalizations in turtles unrelated to mating have not often been reported. Recently, an underwater acoustic repertoire of the Long-necked Turtle, *Chelodina oblonga*, was reported (Giles et al. 2009. J. Acoust. Soc. Am. 126:434–443). However, to my knowledge, communication between mother and juvenile tortoises has not been previously observed. There is no way of knowing, from these observations, whether the female tortoise recognized the hatchlings as her own offspring, or whether she would react the same to any conspecific hatchlings. I hope to record these vocalizations when new hatchlings next appear. Meanwhile though, this anecdotal observation serves to emphasize how much social behavior and the part played by vocalizations remains to be described in tortoises.

GEORGE WATT, Riverine Place # 2202, 9/260 Phibulsongkhram Road, Nonthaburi 11000, Thailand; e-mail: gwattth@yahoo.com.

***TOMISTOMA SCHLEGELII* (False Gharial). DIET.** Few published observations are available on the diet, feeding, or predatory behavior of *Tomistoma schlegelii*, a little-known and threatened Southeast Asian crocodilian (Bezuijen et al. 2010. *In* S. C. Manolis and C. Stevenson [eds.], Crocodiles: Status Survey and Conservation Action Plan, 3rd ed., pp. 133–138. Crocodile Specialist Group, Darwin). Müller (1838. Waarnemingen over de Indische Krokodillen en Beschrijving van Eene Nieuwe Soort. Tijdschrift voor Natuurlijke Geschiedenis en Physiologie 5:61–87) stated the diet of *T. schlegelii* included fish, monitor lizards (*Varanus* spp.), water birds, and mammals. Predation of at least two wild primate species by *T. schlegelii* has been documented by direct observation in the wild and/or through stomach content analysis of wild specimens (Galdikas 1985. Primates 26[4]:495–496; Galdikas and Yeager 1984. Amer. J. Primatol. 6:49–51; Rachawan and Brend 2009. CSG Newsletter 28[1]:9–11). Stomach contents of juvenile wild *T. schlegelii* included shrimp (Bezuijen et al. 1998). There is a single confirmed report of predation on *Homo sapiens*

PHOTO BY MITTAL GALA

FIG. 1. Captive male *Tomistoma schlegelii* with an adult *Melanochelys trijuga* that it captured on land, attempting to break the turtle's carapace after entering the water.

by a *T. schlegelii* from Central Kalimantan Province, Indonesia (Rachawan and Brend 2009. CSG Newsletter 28[1]:9–11). Based on the distinctive narrow snout, some early reports stated that *T. schlegelii* is predominantly piscivorous (Neill 1971. The Last of the Ruling Reptiles: Alligators, Crocodiles, and Their Kin. Columbia University Press, New York. 486 pp.; Campbell and Winterbotham 1985. Jaws, Too! The Natural History of Crocodilians with Emphasis on Sanibel Island's Alligators. Sutherland Publishing, Ft. Myers, Florida. 267 pp.; Guggisberg 1972. Crocodiles: Their Natural History, Folklore and Conservation. Stackpole Books, Harrisburg, Pennsylvania. 195 pp.). Here I report on the first observation of predation on an Indian Pond turtle (*Melanochelys trijuga*) by a captive *T. schlegelii*.

Two captive *T. schlegelii* (a male, 3.8 m total length [TL] and female, 2.8 m TL) housed at the Madras Crocodile Bank Trust and Centre for Herpetology, India, are fed fish, whole chicken, and the occasional Lesser Bandicoot Rat (*Bandicota bengalensis*). The enclosure also houses several *M. trijuga*, which are successfully breeding within the enclosure. In September 2011, two separate incidents of predation on these turtles, by the male and female *T. schlegelii*, were observed.

In the first incident (15 Sept 2011, 1200 h), the female *T. schlegelii* caught a juvenile *M. trijuga* (straight carapace length [SCL] visually estimated to be 125 mm) in the pond, and held in its jaws for approximately 20 minutes, repeatedly cracking the carapace in many points before swallowing it whole. In the second incident (29 Sept 2011, 1200 h), the male caught a turtle (SCL visually estimated to be 250 mm) on land then entered the water, and alternately circled the pond and submerged and emerged, bubbling and hissing, with the (now dead) turtle in its jaws (Fig. 1). It repeatedly attempted to crack the carapace. After several minutes the male emerged without the turtle in his mouth. It is not known whether the turtle was swallowed or dropped, although *T. schlegelii* has been observed to swallow prey underwater (Brueggen 2003. CSG Newsletter 22[1]:21).

Recent information suggests *T. schlegelii* has a broad diet. The distribution of *M. trijuga* does not overlap with *T. schlegelli*, (Das and Bhupathy 2009. *In* Rodin et al. [eds.], Conservation Biology of Freshwater Turtles and Tortoises: A Compilation Project of the IUCN/SSC Tortoise and Freshwater Turtle Specialist Group, pp. 038.1–038.9. Chelonian Research Monographs No. 5), so it is unlikely that *M. trijuga* is a natural prey species in the wild. However, the present observations indicate that turtles are likely to be natural prey for wild *T. schlegelii*.

SQUAMATA — SNAKES

***AGKISTRODON TAYLORI* (Taylor's Cantil). LONGEVITY.** An adult male *Agkistrodon taylori* was confiscated by UK wildlife authorities in February 1995 and donated to the collection at West Midland Safari Park (WMSP), Worcestershire, England. *Agkistrodon taylori* exhibits both sexual and ontogenetic dichromatism (Burchfield 1982. J. Herpetol. 16[4]:376–282) which clearly identified this specimen as an adult male upon arrival. After suitable quarantine, it was introduced to a female of the same species that had been in the collection since 1994. After mating in April 1996 without issue, the pair mated again on 14 March 1997, and were then separated. The female gave birth to nine neonates after 199 days, on 9 September, the first UK captive breeding of the species (O'Shea 1998. The Herptile 23[1]:16–19) and died a few years later, but the male remained in the off-show collection until 4 July 2012 when it was euthanized on health grounds, after 17 yr, 5 mo in captivity at WMSP.

Because this snake was an adult when it arrived, and the earliest the related *A. bilineatus* (Mexican Cantil) reaches sexual maturity is at 30 months (Peters 1979. Internatl. Zoo Yearbk. 19:100–101), a conservative estimate for this specimen's individual's total age could be 19 yr, 11 mo. The previous longevity record for this species is 15 yr, 7 mo, 13 d, for a male at the Houston Zoo, Houston, Texas, USA (Snider and Bowler 1992. Longevity of Reptiles and Amphibians in North American Collections. SSAR Herpetol. Circ. 21:1–40), while a lifespan of 24 yr, 4 mo, 19 d is documented for a *A. bilineatus* at the Instituto Historia Natural, Chiapas, Mexico (*ibid*). The North American members of the genus achieve similar longevities in captivity (*A. contortrix* 29 yr, 10 mo; *A. piscivorus* 24 yr, 6 mo; Snider and Bowler, *op. cit.*).

MARK O'SHEA (e-mail: mark.oshea@wmsp.co.uk), **STEVE SLATER** (e-mail: steve.slater@wmsp.co.uk), and **JAMIE WOOD** (e-mail: jamie.wood@wmsp.co.uk), Mark O'Shea's Reptile World, Discovery Trail, West Midland Safari Park, Bewdley, Worcestershire, DY12 1LF, United Kingdom.

AMPHIBIAN DISEASES

Batrachochytrium dendrobatidis in the Adirondacks, New York, USA

The occurrence of *Batrachochytrium dendrobatidis* (*Bd*) in New York, USA is not well described (www.Bd-maps.net; accessed 22 April 2012). I surveyed for *Bd* in the Adirondack Mountains, New York, at two sites (Fig. 1).

I surveyed for frogs in Keene Valley, New York at Chapel Pond (44.139°N, 73.747°W; 488 m elev.) on 3 August 2011 and Giant Wash Bowl (44.073°N, 73.735°W; 731 m elev.) on 27 August 2011. Frogs were captured and placed in separate Zip-Loc® bags for temporary holding. Disposable gloves were used and changed after each specimen was handled. Skin swabs were collected by swabbing the rear foot, ventral surface of thigh, and ventral abdominal surface of each frog. Each swab was placed in a 2-ml vial with 70% EtOH. Mutations, sluggishness, and leathering of the skin of frogs were noted before their release at the site. None were present. To assess *Bd*-DNA presence, qPCR (modified from Hyman and Collins 2012) was conducted at the School of Life Sciences, Arizona State University.

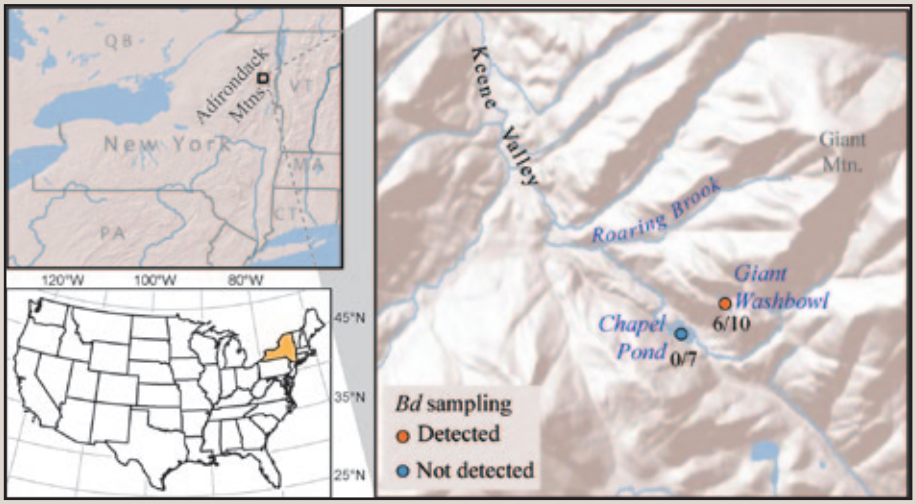

FIG. 1. *Batrachochytrium dendrobatidis* (*Bd*) sampling ponds in the Adirondack Mountains, New York, USA. Numbers indicate number of *Bd*-positive *Rana clamitans*/total number of *R. clamitans* sampled per pond.

At Giant Wash Bowl, 6 of 10 post-metamorphic Green Frogs (*Rana clamitans*) were positive for *Bd*, with zoospore loads ranging from 72-200 Genome Equivalents. All seven Green Frogs (one adult female, six metamorphs) collected from Chapel Pond were *Bd*-negative, although this low sample size may have precluded *Bd* detection if it occurred at a low level (Skerratt et al. 2008).

This is the first study to confirm the presence of *Bd* in the Adirondacks in New York. *Bd* has been detected in Green Frogs previously (e.g., Ouelett et al. 2005). Future studies would benefit from a larger sample size, collecting data over a longer period of time, sampling more species and life stages, and sampling different elevations and locations in the Adirondacks that likely have different climate conditions which may affect *Bd* growth. It would be interesting to conduct a more systematic study of *Bd* throughout all of New York to contribute to an assessment of the potential threat this disease poses to the State's native amphibian diversity.

GEOGRAPHIC DISTRIBUTION

CAUDATA — SALAMANDERS

***AMBYSTOMA MACULATUM* (Spotted Salamander)**. USA: WISCONSIN: Taylor Co.: Chequamegon-Nicolet National Forest, S side of Forest Rd. 102 (Mondeaux Ave.) at 0.3 km NE from jct with Forest Rd. 566 (45.29178°N, 90.44624°W; WGS 84). 28 April 2012. Collected by Erik R. Wild. Verified by Joshua M. Kapfer. UW-Whitewater (UWSP 4289). New county record (Casper 1996. Geographic Distributions of the Amphibians and Reptiles of Wisconsin. Milwaukee Publ. Mus., Milwaukee, Wisconsin. 87 pp.; Herpetological Review 1996–present). Egg clutch was collected from among three other clutches at locality. Additional eggs clutches were observed at other locations in the area (UWSP Herp Photo 0157–0158). Specimen collected under Wisconsin Department of Natural Resources Permit SCP-131-WCR-C-11.

ERIK R. WILD, Department of Biology & UWSP Museum of Natural History, University of Wisconsin-Stevens Point, Stevens Point, Wisconsin 54481, USA; e-mail ewild@uwsp.edu.

***AMBYSTOMA OPACUM* (Marbled Salamander)**. USA: NORTH CAROLINA: McDowell Co.: Private forest, 2 km airline SSE Vein Mountain community (35.53474547°N, 81.95798924°W; WGS 84). 9 June 2012. Lori Williams, Rebecca Hardman, Lloyd Hill, Margaret Stroebel. Verified by William M. Palmer. North Carolina State Museum of Natural Sciences (NCSM 79565). First vouchered specimen for McDowell Co. (NCSM files). This record fills a distributional gap in North Carolina between the Piedmont and Mountain regions. Closest previous historical records in the state are from French Broad River floodplain and upland forest, Buncombe Co., 62 km airline W (NCSM 52284, 59016); and from marshy pasture in Gaston Co., ca. 73 km airline ESE (NCSM 32772, 32825, and 32889). Juvenile (TL = 63.7 mm, SVL = 38.8 mm) found during visual encounter surveys of downed woody debris on mixed hardwood/oak forested hillside, approximately 50 m upslope of dry, bottomland seep.

***PSEUDOBRANCHUS AXANTHUS BELLI* (Everglades Dwarf Siren)**. USA: FLORIDA: Palm Beach Co.: J. W. Corbett WMA (26.844°N, 80.315°W; WGS 84). 5 April 2012. Joshua Young, Joshua Holbrook, Brett Bartek, and Melissa Dolinsky. Verified by Kenneth Krysko. Florida Museum of Natural History (UF 166813). New county record (Krysko et al. 2011. Atlas of Amphibians and Reptiles in Florida. Final report, Project Agreement 08013, Florida Fish and Wildlife Conservation Commission, Tallahassee, Florida. 524 pp.) Nearest known records are from St. Lucie Co. to the north and Miami-Dade Co. to the south. Several dozen individuals were observed in shallow marshy pond habitat with approximately 4–6 inches of peat above a sand substrate. The ponds are temporary, and lack predatory fish. Individuals were collected with a dip net while kicking up mounds of peat. Individuals were also seen swimming in open water between 2130 h and 0530 h. A second population (10 individual observed; UF 167203) was found on 12 June 2012 at Grassy Waters Preserve (26.82955°N, 80.18589°W; Palm Beach Co.).

JOSHUA D. HOLBROOK, Department of Biological Sciences, Florida Atlantic University, Davie, Florida 33314, USA (e-mail: JHolbro8@fau.edu); **JOSHUA YOUNG**, **BRETT BARTEK,** and **MELISSA DOLINSKY,** Palm Beach Zoo, West Palm Beach, Florida 3340, USA.

***SIREN INTERMEDIA* (Lesser Siren)**. USA: VIRGINIA: Dinwiddie Co.: Petersburg National Battlefield (PETE), Five Forks Battlefield, 6.4 km SW Sutherland (37.153581°N, 77.614917°W; WGS 84). 26 August 2003. J. C. Mitchell, C. T. Georgel, E. J. Lathum, C. d'Orgeix, J. Jeffries, and T. Blumenshine. Verified by Kenneth L. Krysko. Florida Museum of Natural History (UF 167206). New county record (Mitchell and Reay 1999. Atlas of Amphibians and Reptiles in Virginia. Virginia Dept. of Game and Inland Fisheries, Richmond, Virginia. Spec. Publ. 1. 122 pp.). This site is 25 km SW of the nearest known location in Prince George Co. Extends the range of *S. intermedia* approximately 17 km into the Piedmont Physiographic Province. One individual with 35 costal grooves was caught in a minnow trap and released in a heavily vegetated beaver pond.

Field work was supported by a contract from the National Park Service and conducted by permits from the NPS (PETE-2002-SCI-003).

JOSEPH C. MITCHELL, P.O. Box 2520, High Springs, Florida 32655, USA; e-mail: dr.joe.mitchell@gmail.com.

ANURA — FROGS

***ACANTHIXALUS SPINOSUS* (African Warty Tree Frog)**. GABON: OGOOUÉ-IVINDO PROVINCE: Ivindo National Park, W of Ipassa Research Station (0.511089°N, 12.801772°E, WGS84; 538 m elev.). 7 April 2010. P. Carlino. Museo di Storia naturale del Salento, Calimera (MSNS-Amph 03). Verified by A. Durante (MSNS). SVL 32.2 mm. At night, on leaf, 1 m above forest floor. First record for Ivindo National Park and Ogooué-Ivindo Province. Closest documented record in Gabon is in Moukalaba-Doudou National Park, Ogooué-Maritime Province, ca. 380 km SW of Ipassa (Pauwels and Rödel 2007. Herpetozoa 19:135–148).

We thank Daniel Franck Idiata, Aurélie Flore Koumba Pambo (CENAREST, Libreville), Auguste Ndoutoume-Ndong (IRAF, Libreville), Alfred Ngomanda (IRET), Joseph Vivien Okouyi Okouyi (Ivindo National Park), and Antonio Durante (MSNS) for providing research and collecting permits.

McCRANIE, 10770 SW 164th Street, Miami, Florida 33157–2933, USA (e-mail: jmccrani@bellsouth.net); **LEONEL MARINEROS**, Oficina de Investigación y Monitoreo PROLANSATE, Tela, Honduras (e-mail: lmarineros@gmail.com); **LEONARDO VALDÉS ORELLANA**, Gerente General de "Hondufauna," Investigador Privado, Colonia América, Bloque 9, Casa 1806, Comayagüela, MDC, Honduras (e-mail: leovalor@hotmail.com).

***SCINAX AURATUS* (Golden Tree Frog)**. BRAZIL: RIO GRANDE DO NORTE: Macaíba, Escola Agrícola de Jundiaí (93.24142°N, 224.8828°W; datum WGS84). 15 July 2010. W. Pessoa. Coleção Herpetológica da Universidade Federal do Rio Grande do Norte, Natal, Rio Grande do Norte, Brazil (CHBEZ 3861). Verified by U. Caramaschi. This Brazilian endemic species was previously known from the states of Bahia, Sergipe, Alagoas, Minas Gerais, and Paraíba (Alves et al. 2004. Rev. Brasil. Zool. 21[2]:315–317; Juncá 2005. *In* Juncá et al. [org.], Biodiversidade e Conservação da Chapada Diamantina, pp. 337–356. Ministério do Meio Ambiente do Brasil, Brasília; Nunes and Pombal Jr. 2010. Amphibia-Reptilia 31:347–353; Protázio et al. 2011. Herpetol. Rev. 42[1]:108–109; Santana et al. 2009. Check List 5[2]:246–248). First state record, extends the geographical distribution ca. 125 km from the municipality of Mamanguape, Paraíba state (Protázio et al. 2011, *op. cit.*).

JAQUEIUTO S. JORGE (e-mail: queilto@yahoo.com.br), **MATHEUS MEIRA**, and **ELIZA M. X. FREIRE**, Laboratório de Herpetologia, Departamento de Botânica, Ecologia e Zoologia, Centro de Biociências, Universidade Federal do Rio Grande do Norte, Campus Universitário, Lagoa Nova, CEP 59072-970, Natal, Rio Grande do Norte, Brazil.

***SPEA BOMBIFRONS* (Plains Spadefoot)**. USA: NEW MEXICO: Catron Co.: Goat Tank Canyon, ca. 0.4 km E of Pie Town Rd. (Rd. 41) (34.57495°N, 108.00669°W, NAD83; elev. 2209 m). 7 July 2011. Ian W. Murray and Christopher Newsom. Verified by J. Tomasz Giermakowski. University of New Mexico Museum of Southwestern Biology (MSB 78830, 78831). New county record (Degenhardt et al. 1996. Amphibians and Reptiles of New Mexico. Univ. New Mexico Press, Albuquerque. 431 pp.). Two calling males were collected from a large pool in a broad wash, which had formed from heavy rains within the previous two days. A large chorus of calling *S. bombifrons* and *S. multiplicata* were observed at 2345 h (~5 *S. multiplicata* for every *S. bombifrons*). Many clumps of eggs had already been laid around emergent grasses and weeds. Additionally, more calling and grappling males were noted relative to amplectant pairs, implying that this night was probably the second night of amphibian breeding activity.

***GRAPTEMYS GEOGRAPHICA* (Northern Map Turtle)**. USA: TENNESSEE: Polk Co.: Reliance (35.19654°N, 84.45650°W; WGS

84). 23 May 2012. Stephen K. Nelson, Ben Fitzpatrick, and Phil Colclough. Verified by A. Floyd Scott. David H. Snyder Museum of Zoology, Austin Peay State University (APSU 19304, 19305, photo vouchers). First county record (Redmond and Scott 2008. Atlas of Reptiles in Tennessee. The Center for Field Biology, Austin Peay State University, Clarksville, Tennessee. Available at http://apsu.edu/repatlas/ (updated 07 August 2012; accessed 24 August 2012). An adult female was found crossing a road at 1500 h. A second specimen, a juvenile, was found basking on a log jam (35.19413°N, 84.47128° W) on 6 June 2012. Extends the range ca 87 km to the east (Wilson et al. 2012. Herpetol. Rev. 43[1]:111–112) and to the southeast ca. 57 km (Redmond and Scott 2008, *op. cit.*). This is the first report of *G. geographica* in extreme southeastern Tennessee.

STEPHEN K. NELSON, Department of Forestry, Wildlife and Fisheries, University of Tennessee, Knoxville, Tennessee 37996-0925, USA; Department of Herpetology, Knoxville Zoological Gardens, Knoxville, Tennessee 37914-4416, USA (e-mail: snelso24@utk.edu); **BEN FITZPATRICK**, Department of Ecology and Evolutionary Biology, University of Tennessee, Knoxville, Tennessee 37996-0925, USA (e-mail: bfitz@utk.ed); **PHILLIP COLCLOUGH**, Department of Herpetology, Knoxville Zoological Gardens, Knoxville, Tennessee 37914-4416, USA (e-mail: pcolclough@knoxville-zoo.org).

***GRAPTEMYS OUACHITENSIS* (Ouachita Map Turtle)**. USA: MISSOURI: Adair Co.: S. Baltimore St. at intersection of Franklin St., Kirksville (40.163528°N, 92.571889°W; WGS 84). 31 July 2012. Anthony J. Wilmes and Chad E. Montgomery. Verified by Jeff Briggler. University of Missouri Columbia (UMC 2196P photo voucher). First county record (Daniel and Edmond 2012. Atlas of Missouri Amphibians and Reptiles for 2011. http://atlas.moherp.org/pubs/atlas11.pdf, accessed 10 September 2012). Adult male (carapace length 117 mm; mass 167.1 g). Extends known range by ca. 100 km. Due to the distance from permanent water habitat to the locality (~5–15 km depending on water source) it is possible that this individual represents a release rather than a naturally occurring population.

ANTHONY J. WILMES (e-mail: awilmes@truman.edu) and **CHAD E. MONTGOMERY,** Department of Biology, Truman State University, Kirksville, Missouri 63501, USA (e-mail: chadmont@truman.edu).

***GRAPTEMYS PSEUDOGEOGRAPHICA PSEUDOGEOGRAPHICA* (False Map Turtle)**. USA: FLORIDA: Volusia Co.: Blue Springs State Park, 200 m E of the mouth of St. Johns River inside of the Blue Spring Run (28.94337°N, 81.341264°W; WGS84; elev. 6 m). 27 May 2011. Eric C. Munscher. Verified by Gerald R. Johnson and Kenneth L. Krysko. Florida Museum of Natural History (UF 168572). New county record (Krysko et al. 2011. Atlas of Amphibians and Reptiles in Florida. Final report, Florida Fish and Wildlife Conservation Commission, Tallahassee, Florida. 524 pp.). Female (max carapace length = 233 mm, straight midline plastron length = 178 mm, mass = 927 g) captured by hand at 1000 h along the center of the lower Blue Spring Run toward the St. Johns River. The abundance of algae on the carapace (60% of surface area) suggests this is not a recently released captive. This is the first reported occurrence of *G. p. pseudogeographica* in the St. Johns River Basin. This non-indigenous turtle may be in the early phase of an introduction and may require monitoring. In Florida, *G. p. pseudogeographica* is commonly sold in pet stores and may replace the Red-eared Slider (*Trachemys scripta elegans*) as the most frequently released non-indigenous pet turtle. Given its omnivorous diet and the proximity to similar adequate habitat types (St. Johns River) to its native habitat in the Missouri and Mississippi River drainages, *G. p. pseudogeographica* could potentially thrive in the St. Johns River Basin.

ERIC C. MUNSCHER, Department of Natural Resources, SWCA Environmental Consultants, Houston, Texas 77068, USA (e-mail: emunscher@swca.com); **J. BRIAN HAUGE**, Peninsula College, Port Angeles, Washington 98362, USA (e-mail: biologybrian@gmail.com); **KATY BERGIN**, Blue Springs State Park, 2100 West French Ave., Orange City, Florida USA (e-mail: megan.keserauskis@dep.state.fl.us).

***PELODISCUS SINENSIS* (Chinese Softshell Turtle)**. BRAZIL: PARÁ: Municipality of Belém: 1.366°S, 48.392°W; datum WGS 84). Museu Paraense Emílio Goeldi, Belém, Pará, Brazil (MPEG 1214–1216). 10 February 2010. D. Félix-Silva, J. C. B. Pezutti, M. F. Wariss, E. J. Hernández-Ruz. Verified by M. S. Hoogmoed. Previously known from central and eastern China, Vietnam, and the islands of Hainan and Taiwan (Bonin et al. 2006. Turtles of the World. John Hopkins University Press, Baltimore, Maryland. 416 pp.; Vetter and van Dijk 2006. Turtles of the World, Vol. 4: East and South Asia. Edition Chimaira, Frankfurt am Main. 162 pp.) and was introduced to Thailand, Japan, and Hawaii, southeastern Siberia, Russia, and Korea (Fritz et al. 2010. Organisms, Diversity and Evolution 10:227–242). First vouchered record for Brazil and South America. Although mentioned as occurring in Brazil (Uetz 2012. The Reptile Database. Online database at: http://www.reptile-database.org/. Accessed 6 June 2012), this record appears to be unsupported by a voucher or bibliographic citation.

***STERNOTHERUS ODORATUS* (Eastern Musk Turtle)**. USA: TENNESSEE: Blount Co.: Townsend (35.68013°N, 83.78225°W; WGS84). 12 August 2012. Stephen K. Nelson and Bradley D. Moxley. Verified by A. Floyd Scott. David H. Snyder Museum of Zoology, Austin Peay State University (APSU 19303, color photo). First county record (Redmond and Scott 2008. Atlas of Reptiles in Tennessee. The Center for Field Biology, Austin Peay State University, Clarksville, Tennessee. Internet version, available at http://apsu.edu/repatlas/ [updated 07 August 2012]; accessed 24 August 2012). Found foraging at night on sandy substrate. Three leaches were attached to plastron.

STEPHEN K. NELSON, Department of Forestry, Wildlife, and Fisheries, University of Tennessee, Knoxville, Tennessee 37996-0925, USA; Department of Herpetology, Knoxville Zoological Gardens, Knoxville, Tennessee

37914-4416, USA (e-mail: snelso24@utk.edu); **BRADLEY D. MOXLEY**, Department of Herpetology, Knoxville Zoological Gardens, Knoxville, Tennessee 37914-4416, USA (e-mail: bmoxley@knoxville-zoo.org).

***TERRAPENE CAROLINA* (Eastern Box Turtle)**. USA: ALABAMA: Tallapoosa Co.: Rotton Creek (33.05366°N, 85.84159°W; WGS 84). 29 June 2012. Ian E. P. Turner. Verified by Craig Guyer. Auburn University herpetological collection (AHAP-D 00591 photo voucher). Two adult males were found along floodplain of creek. New county record (Mount 1975. The Reptiles and Amphibians of Alabama. Auburn University Agricultural Experiment Station, Auburn, Alabama. vii + 347 pp.). *Terrapene carolina* is assumed to occur statewide in Alabama, but verified records are lacking for many counties.

IAN E P. TURNER, Department of Agronomy and Soils, Auburn University, Alabama 36849, USA (e-mail: iep.turner@gmail.com); **BRIAN P. FOLT,** Department of Biological Sciences, Auburn University, Auburn, Alabama 36849, USA (e-mail: brian.folt@gmail.com).

***TERRAPENE CAROLINA TRIUNGUIS* (Three-toed Box Turtle)**. USA: OKLAHOMA: Jefferson Co.: 3.22 km N and 2.41 km E of Terral, Oklahoma in an open field (33.92559°N, 97.91999°W; WGS 84). 18 July 2009. Cameron University Museum of Zoology (CUMZ 216). Collected by D. Doug Gunter. Verified by Stanley F. Fox. New county record (Sievert and Sievert 2011. A Field Guide to Oklahoma's Amphibians and Reptiles, 3rd ed. Oklahoma Department of Wildlife Conservation. Oklahoma City, Oklahoma. 211 pp.). Previously documented populations from adjacent Oklahoma counties to the north (Stephens Co.) and east (Carter and Love counties) as well as Cooke Co., Texas to the immediate southeast (Dixon 2000. Amphibians and Reptiles of Texas. Texas A&M Press, College Station. 419 pp.).

JARED W. WHITE (e-mail: Jared.White@cameron.edu), **D. DOUG GUNTER** and **MICHEAL S. HUSAK,** Department of Biological Sciences, Cameron University, Lawton, Oklahoma 73505, USA (e-mail: michealh@cameron.edu).

***TRACHEMYS SCRIPTA ELEGANS* (Red-eared Slider)** USA: FLORIDA: Seminole Co.: Wekiwa Springs State Park, 0.17 km from the Wekiwa Springs boil (28.71361°N, 81.45859°W; WGS84; elev. 6 m). 26 March 2011. Eric C. Munscher. Verified by Kenneth L. Krysko, Florida Museum of Natural History (UF 168593). New county record (Krysko et al. 2011. Atlas of Amphibians and Reptiles in Florida. Final report, Florida Fish and Wildlife Conservation Commission, Tallahassee, Florida. 524 pp.). Female (max carapace length = 242 mm, straight midline plastron length = 183 mm, mass = 1023 g) captured by hand at 1030 h along the eastern end of the Wekiwa Springs Lagoon. The lack of algal growth on this turtle's shell could indicate a recent release. In Florida, *T. s. elegans* has been commonly sold in pet stores for many years and as a result has become one of the most frequently released exotic species of turtle in the state.

ERIC C. MUNSCHER, Department of Natural Resources, SWCA Environmental Consultants, Houston, Texas 77068, USA (e-mail: emunscher@swca.com); **J. BRIAN HAUGE**, Peninsula College, Port Angeles, Washington 98362, USA (e-mail: biologybrian@gmail.com); **JOSEPH McDONALD**, Western Washington University, Huxley College of the Environment, Bellingham, Washington 98255, USA.

***TRACHEMYS SCRIPTA ELEGANS* (Red-eared Slider)**. USA: GEORGIA: Hall Co.: Reservoir One on Calvary Church Rd (34.22629°N, 83.82584°W; WGS 84). 3 August 2012. Todd Pierson and Daniel Thompson. Verified by Kenneth Krysko. Florida Museum of Natural History (UF 168565 photo voucher); New county record (Jensen et al. 2008. Amphibians and Reptiles of Georgia. University of Georgia Press, Athens. 575 pp). More than five individuals of this non-native subspecies were observed, and this record likely represents an established population.

TODD PIERSON, Odum School of Ecology, University of Georgia, Athens, Georgia 30609, USA (e-mail: twpierso@uga.edu); **DANIEL THOMPSON**, Chestatee High School, Gainesville, Georgia 30506, USA (e-mail: danielsthompson@gmail.com).

SQUAMATA — LIZARDS

***ASPIDOSCELIS SEXLINEATA* (Six-lined Racerunner)**. USA: GEORGIA: Hall Co.: Reservoir One on Calvary Church Rd (34.22743°N, 83.82511°W; WGS 84). 3 August 2012. Todd Pierson and Daniel Thompson. University of Georgia Press, Athens. 575 pp.).

TODD PIERSON, Odum School of Ecology, University of Georgia, Athens, Georgia 30609, USA (e-mail: twpierso@uga.edu); **DANIEL THOMPSON**, Chestatee High School, Gainesville, Georgia 30506, USA (e-mail: danielsthompson@gmail.com).

***CERCOSAURA OCELLATA* (Ocellated Tegu)**. BRAZIL: SERGIPE: Municipality of Areia Branca: Parque Nacional Serra de Itabaiana (PARNASI, 10.7488°S, 373447°W, 240 m elev.; datum SAD-69). 19 October 2008. M. V. Noronha-Oliveira. Herpetological Collection of the Universidade Federal of Sergipe, São Cristóvão, Sergipe, Brazil (C00191, collected in pitfall traps). Verified by D. Oliveira Mesquita. *Cercosaura ocellata* has wide distribution in Brazil, occurring in the states of Goiás (Vaz-Silva et al. 2007. Check List 3[4]:338–345), Distrito Federal (Colli et al. 2011. *In* M. E. Ribeiro [ed.], Reserva Ecológica do IBGE, Biodiversidade Terreste, pp. 130–145. IBGE. Rio de Janeiro. Brazil. 580 pp.), Mato Grosso do Sul (Uetanabaro et al. 2007. Biota Neotrop. 7[3]:279–289), Mato Grosso (Ávila and Silva 2011. Comp. Parasitol. 78[1]:129–139), Acre (Bernarde et al. 2011. Biota Neotrop. 11[3]:117–144), Rondônia (Macedo et al. 2008. Biota Neotrop 8[1]:133–139), Pará (Mendes-Pinto and Souza 2011. Salamandra 47[4]:199–206), Tocantins (Recoder et al. 2011. Biota Neotrop. 11[1]:263–282), Bahia (Couto-Ferreira et al. 2011. J. Threatened Taxa 3[8]:1990–2000), Ceará (Loebmann and Haddad 2010. Biota Neotrop. 10[3]:227–256), Minas Gerais (Souza et al. 2010. Biota Neotrop. 10[2]:129–138), Amapá (Gardner et al. 2007. Conserv. Biol. 21[3]:775–787), Amazonas, Maranhão, and Roraima (Avila-Pires 1995. Lizards of Brazilian Amazonia [Reptilia: Squamata]. Zool. Verh. 299:1–706), Rio Grande do Sul and São Paulo (Molina 2001. Herpetol. Rev. 32[4]:275), and other countries of South America: Paraguay (Motte et al. 2009. Cuad. Herpetol. 23[1]:5–18), Venezuela (Gorzula and Senāris 1998. Sci. Guianae 8:1–270), Bolivia (Langstroth 2005. Kempffiana 1[1]:101–128) Peru (Duellman and Salas 1991. Occas. Papers. Mus. Nat. Hist. Univ. Kansas 143:1–13), and Suriname, British Guiana, and French Guiana (Ávila-Pires 2005. *In* Hollowell and Reynolds [eds.], Checklist of the Terrestrial Vertebrates of the Guiana Shield, pp. 25–40. Bull. Biol. Soc. Washington 13). First state record, extends distribution of *C. ocellata* ca. 270 km from municipality Mata de São João, on the northern coast of Bahia, Brazil (Couto-Ferreira et al., *op. cit.*). However, large distributional gaps remain, indicating the need for additional field surveys (Noronha-Oliveira et al. 2010. Herpetol. Rev. 41[3]:512).

Collecting permit (#10504-1) was granted by Instituto Brasileiro do Meio Ambiente e dos Recursos Naturais Renováveis – IBAMA.

MARCUS VINÍCIUS NORONHA-OLIVEIRA, Departamento de Biologia, Laboratório de Herpetologia, Universidade Federal de Sergipe, 49.000-000, São Cristóvão, Sergipe, Brazil (e-mail: mv_bioufs@hotmail.com); **CRIZANTO BRITO DE-CARVALHO, EVELLYN BORGES DE FREITAS,** and **RENATO GOMES FARIA,** Núcleo de Pós-Graduação em Ecologia e Conservação, Universidade Federal de Sergipe, 49.000-000, São Cristóvão, Sergipe, Brazil.

***COPHOSAURUS TEXANUS* (Greater Earless Lizard)**. USA: NEW MEXICO: Cibola Co.: 13.7 km SSW of Correo and 4.1 km NNW of Black Mesa, W of Mesa Lucero in western Valencia Co. (34.8456°N, 107.2524°W, WGS84; elev. 1800 m). 2 August 2010. J Tomasz Giermakowski and Jobette Chour. Verified by Charles W Painter. University of New Mexico Museum of Southwestern Biology (MSB 77916). New county record (Degenhardt et al. 1996. Amphibians and Reptiles of New Mexico. Univ. New Mexico Press, Albuquerque. xix + 431 pp.). This represents the first record in the volcanic areas of eastern Cibola Co. and extends the known range by approximately 25 km WNW of the nearest verified locality at Hidden Mountain, Valencia Co., New Mexico (MSB 77903). This record and a recent specimen from northwestern Socorro Co. (MSB 79209) suggest that *Cophosaurus texanus* may be distributed more widely and at higher elevations throughout Rio Grande drainages than previously documented.

Collected under permits from the New Mexico Department of Game and Fish (Authorization 3329) and The University of New Mexico (IACUC Protocol 10-100453-MCC).

J. TOMASZ GIERMAKOWSKI, MSC03 2020, Museum of Southwestern Biology, 1 University of New Mexico, Albuquerque, New Mexico 87131-0001, USA (e-mail: tomas@unm.edu); **JOBETTE CHOUR**, 416 69th St. SW, Albuquerque, New Mexico 87121-2458, USA.

***HEMIDACTYLUS MABOUIA* (Wood Slave)**. USA: FLORIDA: Monroe Co.: Pigeon Key (24.70418°N, 81.15518°W; WGS84). 21 August 2012. Verified by Kenneth Krysko. UF 168591, 168592. New island record (Krysko et al. 2011. Atlas of Amphibians and Reptiles in Florida. Final report, Project Agreement 08013, Florida Fish and Wildlife Conservation Commission, Tallahassee, Florida. 524 pp.; K. L. Krysko, pers. comm.). Vouchers captured under coral limestone garden rocks. Numerous individuals of this introduced species were located on and around island buildings.

I thank Kelly McKinnon and the Pigeon Key Foundation for their assistance and hospitality.

KIRSTEN A. HECHT-KARDASZ, Florida Museum of Natural History, University of Florida, Gainesville, Florida 32611, USA; e-mail: kirstenkardasz@gmail.com.

***HEMIDACTYLUS TURCICUS* (Mediterranean Gecko)**. USA: ALABAMA: Covington Co.: Rome Pond, 0.5 km N of U.S. Hwy 29 (31.14377°N, 86.67436°W; WGS 84). 29 June 2012. S. Graham and G. Brooks. Verified by Craig Guyer. AUM 39893. New county record (Mount 1975. The Reptiles and Amphibians of Alabama. Auburn Printing Co., Auburn, Alabama. 347 pp.) This specimen is the first record of *Hemidactylus turcicus* within the proclamation boundary of Conecuh National Forest. The individual was collected from the side of a private residence.

Funding for this research was provided by IOS-1051367 to T. Langkilde.

***SCELOPORUS POINSETTII* (Crevice Spiny Lizard)**. USA: NEW MEXICO: Luna Co.: 15.6 km ENE of town of Hachita and approximately 1570 m ESE of peak of Cedar Mountain (31.9669°N, 108.1659°W, WGS 84; elev. 1645 m). 14 May 2011. J Tomasz Giermakowski and Bruce L. Christman. Verified by Charles W. Painter. University of New Mexico Museum of Southwestern Biology (MSB 79208). Second record for Luna Co. (Degenhardt et al. 1996. Amphibians and Reptiles of New Mexico. Univ. New Mexico Press, Albuquerque, xix + 431 pp.).

The first record (ANSP 21121) from Deming, Luna Co., New Mexico was collected by H. A. Pilsbry in 1915. This specimen was likely collected from the nearby Black Range Mountains, in Sierra and Grant counties north of Deming because no suitable habitat existed in the immediate vicinity of Deming and because during August of 1915 Pilsbry is known to have collected in Black Range Mountains (Pilsbry and Ferriss 1917. Proc. Acad. Nat. Sci. Philadelphia 69:83–107). The nearest specimens were collected in July of 1908 and are identified as being from Hachita, Grant Co., New Mexico (USNM 45100–45102). This new specimen and another collected more recently (MSB 79499), both from the eastern portion of Cedar Mountains, represent first verified records for Luna Co. and suggest that the species may be present in other isolated mountain ranges throughout southern New Mexico.

Collected under permits from the New Mexico Department of Game and Fish (Authorization 3329) and The University of New Mexico (IACUC Protocol 10-100453-MCC).

J. TOMASZ GIERMAKOWSKI, Museum of Southwestern Biology, MSC03 2020, University of New Mexico, Albuquerque, New Mexico 87131-0001, USA (e-mail: tomas@unm.edu); **BRUCE L. CHRISTMAN,** 736 Cardenas SE, Albuquerque, New Mexico 87106, USA (e-mail: nattybrew@hotmail.com).

***SCINCELLA LATERALIS* (Little Brown Skink)**. USA: TENNESSEE: Chester Co.: Henderson, Mid-south Youth Camp (35.462163°N, 88.682263°W; WGS 84). 5 April 2012. Brian P. Butterfield, E. Ladd Kuykendall, and Melissa T. Marshall. Verified by A. F. Scott. Austin Peay State University (APSU 19312 photographic voucher). New county record (Scott and Redmond 2008 [latest update: 7 August 2012]. Atlas of Reptiles in Tennessee. Center for Field Biology, Austin Peay State University, Clarksville, Tennessee. Available at http://apsu.edu/reptatlas/, accessed 7 September 2012). Captured within a pile of wood and metal debris.

ERRATUM

In a recently published geographic distribution note (Davis and DeSantis 2012. Herpetol. Rev. 43[2]:449), we identified two snakes in the Texas Natural History Collections (TNHC 85172, 85173) as *Pantherophis emoryi*. However, subsequent examination of TNHC specimens of *P. emoryi, P. guttatus*, and *P. slowinskii*, and consultation with Travis LaDuc suggests that our earlier specimens should be referred to *P. slowinskii* instead. Assignment to species based on external characters in this region of range overlap is difficult. Even with this change of species assignment, these specimens represent a new record for Fayette Co. (Dixon 2000. Amphibians and Reptiles of Texas. Texas A&M University Press, College Station. 421 pp.).

DREW R. DAVIS (e-mail: drewdavis@txstate.edu) and **DOMINIC L. DESANTIS** Texas State University, Department of Biology, 601 University Drive, San Marcos, Texas 78666, USA (e-mail: dd1298@txstate.edu).

New County Records for Ohio Amphibians and Reptiles

The historic and contemporary distributions of Ohio's herpetofauna have been recently summarized in atlases on anurans (Davis and Menze 2000), salamanders (Pfingsten and Matson 2003), and reptiles (Wynn and Moody 2006). The distributions of anurans at the county level were subsequently updated by Davis and Menze (2002). Southeastern Ohio remains only moderately sampled, and distributional gaps exist for many species. In addition, there have been relatively few records added in this region since the pioneering works of Walker (1946), Conant (1951), and Seibert and Brandon (1960). The lack of new records is particularly acute in the case of reptiles. To begin to address this situation, we utilized survey methods such as walking transects in habitat, searching under natural and artificial cover, and nocturnal road driving to detect the presence of amphibians and reptiles throughout Ohio, with emphasis on the southeastern counties. Here, we report 27 new county records since 2004, including at least one new county record for 23 species. Voucher specimens were deposited into the Herpetology Fluid Collections (CMC) and photographs into the Herpetological Photodocumentation Collection (CMC HP) of the Cincinnati Museum Center's Frederick and Amey Geier Research and Collections Center. Tissue samples from specimens were placed into the fluid collection. Identification of all records was verified by Jeffrey G. Davis, unless otherwise indicated. The datum for all GPS coordinates is WGS 84.

CAUDATA — SALAMANDERS

***AMBYSTOMA BARBOURI* (Streamside Salamander)**. USA: OHIO: Jackson Co.: Franklin Township, Clay Banner Rd. 0.5 mi. E of intersection with Franklin Valley Rd. (Co. Rd. 13) (38.94032°N, 82.59140°W). 20 April 2009. C. Brune. CMC 11570, CMC HP 3594–3602. Verified by Katherine R. Greenwald based on mtDNA sequences. New county record (Pfingsten and Matson 2003). This locality extends the known range eastward by approximately 65 km. It lies within the preglacial Marietta River Valley. In contrast to most of southeastern Ohio, the terrain here is relatively flat and rocks appear to be entirely lacking. Additional surveys in March 2010 revealed that this species is broadly distributed in the Franklin Valley area of Franklin and Jefferson Townships of Jackson Co. (CMC 12074, 12075).

***AMBYSTOMA TIGRINUM* (Eastern Tiger Salamander)**. USA: OHIO: Fairfield Co.: Violet Township (39.87822°N, 82.78783°W). 15 March 2008. D. Alessandrini, A. Avram, C. Brune, J. Folt. CMC HP 2732. New county record (Pfingsten and Matson 2003). Animal found alive on Schoolhouse Road during a nocturnal road survey.

***HEMIDACTYLIUM SCUTATUM* (Four-toed Salamander)**. USA: OHIO: Athens Co.: Waterloo Township, Waterloo Wildlife Area, Pine Run floodplain (39.34231°N, 82.28093°W). 15 April 2004. C. Brune. CMC HP 864–870. New county record (Pfingsten and Matson 2003). Pike Co.: Benton Township, Pike State Forest, Tobacco Barn Hollow (39.17510°N, 83.20813°W). 3 May 2008. D. Alessandrini, C. Brune, N. Cornell, B. Folt, J. Folt. CMC HP 3036-3038. New county record (Pfingsten and Matson 2003).

***PLETHODON ELECTROMORPHUS* (Northern Ravine Salamander)**. USA: OHIO: Hocking Co.: Starr Township, Wayne National Forest (39.45346°N, 82.32506°W). 10 November 2007. C. Brune. CMC HP 2677–2681. New county record (Pfingsten and Matson 2003).

***PSEUDOTRITON MONTANUS DIASTICUS* (Midland Mud Salamander)**. USA: OHIO: Pike Co.: Jackson Township (39.09534°N, 82.79655°W). 13 January 2007. C. Brune and J. Folt. CMC HP 2677–2681. New county record (Pfingsten and Matson 2003).

***PSEUDOTRITON RUBER* (Red Salamander)**. USA: OHIO: Monroe Co.: Jackson Township, Fly Gorge in the Wayne National Forest (39.57166°N, 81.00417°W). 25 March 2012.. C. Brune and M. Haughey. CMC HP 7274–7276. New county record (Pfingsten and Matson 2003).

ANURA — FROGS

***ACRIS BLANCHARDI* (Blanchard's Cricket Frog)**. USA: OHIO: Gallia Co.: Raccoon Township, Tycoon Lake Wildlife Area (38.92757°N, 82.34091°W). 3 June 2006. C. Brune. CMC HP 1711-1712. New county record (Davis and Menze 2002).

TESTUDINES — TURTLES

***APALONE SPINIFERA* (Spiny Softshell)**. USA: OHIO: Summit Co.: Boston Township, Cuyahoga Valley National Park (41.20080°N, 81.56860°W). 10 July 2012. Douglas W. Vogus. CMC HP 7286–7287. New county record (Wynn and Moody 2006). Observed basking along a bank of the Cuyahoga River near the Bolanz Road bridge.

***TRACHEMYS SCRIPTA* (Pond Slider)**. USA: OHIO: Clermont Co.: Union Township, Cincinnati Nature Center (39.12618°N,

84.24296°W). 16 July 2006. J. Folt. CMC HP 4441. New county record (Wynn and Moody 2006). Observed swimming in ponds on the park property.

SQUAMATA — LIZARDS

***PLESTIODON LATICEPS* (Broad-headed Skink)**. USA: OHIO: Gallia Co.: Greenfield Township, Wayne National Forest (38.77707°N, 82.53091°W). 20 April 2012. C. Brune. CMC HP 7278–7281. New county record (Wynn and Moody 2006).

SQUAMATA — SNAKES

***AGKISTRODON CONTORTRIX* (Copperhead)**. USA: OHIO: Gallia Co.: Ohio Township, Crown City Wildlife Area (38.60084°N, 82.25623°W). 26 July 2008. C. Brune. CMC HP 3238–3241. New county record (Wynn and Moody 2006).

***CARPHOPHIS AMOENUS* (Eastern Wormsnake)**. USA: OHIO: Gallia Co.: Greenfield Township (38.79158°N, 82.55307°W). 11 July 2009. C. Brune. CMC HP 3835–3838. New county record (Wynn and Moody 2006).

***CROTALUS HORRIDUS* (Timber Rattlesnake)**. USA: OHIO: Lawrence Co.: Symmes Township, Wayne National Forest, approximately 5 km S of Peniel, Ohio (38.7°N, 82.5°W). 3 July 2009. C. Brune, R. Brune, and B. Folt. CMC HP 3799–3807. New county record (Wynn and Moody 2006).

***DIADOPHIS PUNCTATUS* (Ring-necked Snake)**. USA: OHIO: Gallia Co.: Guyan Township (38.63268°N, 82.27974°W). 3 June 2006. C. Brune. CMC HP 1722. New county record (Wynn and Moody 2006).

***LAMPROPELTIS NIGRA* (Eastern Black Kingsnake)**. USA: OHIO: Pike Co.: Jackson Township, Ohio Road 335, north of Beaver, Ohio (39.13026°N, 82.86982°W). 26 June 2006. J. Folt. CMC HP 4415. First vouchered specimen for county (Wynn and Moody 2006). Found dead-on-road.

***LAMPROPELTIS TRIANGULUM* (Eastern Milksnake)**. USA: OHIO: Gallia Co.: Guyan Township (38.63268°N, 82.27974°W). 3 June 2006. C. Brune. CMC HP 1721. New county record (Wynn and Moody 2006).

***HETERODON PLATIRHINOS* (Eastern Hog-nosed Snake)**. USA: OHIO: Gallia Co.: Morgan Township (38.96563°N, 82.31209°W). 24 August 2006. C. Brune. CMC HP 1896–1898.
Lawrence Co.: Washington Township (38.79836°N, 82.61806°W). 13 April 2012. C. Brune. CMC HP 7277. New county records (Wynn and Moody 2006).

***NERODIA SIPEDON* (Northern Watersnake)**. USA: OHIO: Gallia Co.: Perry Township, Raccoon Creek County Park (38.78990°N, 82.34628°W). 3 June 2006. C. Brune. CMC HP 1715–1718. New county record (Wynn and Moody 2006).

***PANTHEROPHIS SPILOIDES* (Gray Ratsnake)**. USA: OHIO: Brown Co.: Lewis Township (38.83357°N, 83.95135°W). 2 June 2007. C. Brune. CMC HP 2467. New county record (Wynn and Moody 2006).

***STORERIA DEKAYI* (DeKay's Brown Snake)**. USA: OHIO: Lawrence Co.: Washington Township, Ironton Forest Wildlife Area (38.78656°N, 82.61074°W). 2 July 2011. C. Brune. CMC 12232–12236, CMC HP 7018. New county record (Wynn and Moody 2006). Mahoning Co.: Youngstown Township (41.09490°N, 80.63385°W). 14 April 2006. J. Folt, R. Folt and R. Novotny. CMC HP 4270. New county record (Wynn and Moody 2006). Found under trash littering abandoned road just off of Lane Road.

***STORERIA OCCIPITOMACULATA* (Red-bellied Snake)**. USA: OHIO: Lawrence Co.: Symmes Township, (38.76764°N, 82.54320°W). 13 June 2009. C. Brune. CMC HP 3787–3791. New county records (Wynn and Moody 2006). Summit Co.: Boston Township, Cuyahoga Valley National Park (41.250748°N, 81.522557°W). 27 May 2010. Jared Mizanin and John Mizanin. CMC HP 7282-7283. New county record (Wynn and Moody 2006). Found beneath discarded wood in a field.

***VIRGINIA VALERIAE* (Smooth Earthsnake)**. USA: OHIO: Lawrence Co.: Washington Township, Ironton Forest Wildlife Area (38.78656°N, 82.61074°W). 2 August 2009. C. Brune and B. Folt. CMC 3880–3881. New county record (Wynn and Moody 2006).

Acknowledgments.—We thank Jeffrey G. Davis for verifying the records and providing liaison with the Cincinnati Museum. CRB obtained the relevant state permit associated with collection of animals noted above.

NATURAL HISTORY NOTES

CAUDATA — SALAMANDERS

***AMBYSTOMA MABEEI* (Mabee's Salamander). REPRODUCTION.** The reproductive biology of Mabee's Salamander is the least studied of all the North American ambystomatids. Breeding migration and mating dates, as well as egg size and mode of egg deposition, have been described by Hardy (1969a. Chesapeake Biol. Lab., Nat. Res. Inst. Univ. Maryland, Solomans, Maryland. Ref. No. 60-20, 3 pp.; Hardy 1969b. Bull. Maryland Herpetol. Soc. 5:65–76), Russell et al. (1998. Herpetol. Rev. 29:36–37), and McCoy (2000. An analysis of migratory behavior, physiological condition, and life history strategy in the salamanders *Ambystoma mabeei* and *A. opacum* in southeastern Virginia. MS Thesis, Old Dominion Univ., Norfolk, Virginia). Clutch size, however, has not been reported for this species (Mitchell 2005. *In* M. Lannoo [ed.], Amphibian Declines: The Conservation Status of United States Species, pp. 616–617. Univ. California Press, Berkeley, California).

On 6 March 1988, we, along with K. A. Buhlmann, J. L. Elwood, and M. D. Poplawski, collected three gravid female *A. mabeei* in Newport News City Park, York Co., Virginia, USA (37.193056°N, 76.513056°W, NAD83). All were found under logs adjacent to a natural sinkhole pond. One unmeasured female deposited 110 infertile eggs in captivity on 15 March 1988 but retained 17 eggs in the oviducts (this specimen died and was lost). Total clutch size was 127. Two additional females were euthanized and dissected. One (67 mm SVL, Carnegie Museum 128266) contained 290 mature eggs (left 144, right 146) and the other (68 mm SVL, CM 128267) contained 163 eggs (left 74, right 89). Mean clutch size was 193.3 ± 85.6 (1 SD). Mean diameter of 11 mature ova in the former was 1.84 ± 0.14 mm and 10 ova in the latter measured 2.06 ± 0.13 mm. Deposited eggs in early cleavage were 5.1–5.9 mm in diameter (Hardy 1969a, *op. cit.*).

These specimens were collected prior to the listing of *A. mabeei* as a threatened species in Virginia (Mitchell 1991. *In* K. Terwilliger [Coord.], Virginia's Endangered Species, pp. 411–423. McDonald and Woodward Publ. Co., Blacksburg, Virgina).

***AMBYSTOMA MACULATUM* (Spotted Salamander). PREDATION.** Amphibians are common prey to an array of taxa including many vertebrates, arthropods, and even carnivorous plants (Duellman and Trueb 1986. Biology of Amphibians. McGraw Hill, New York. 679 pp.; Burgason 1999. *In* M. L. Hunter et al. [eds.],Maine Amphibians and Reptiles, pp. 62–65. Univ. Maine Press, Orono, Maine). Although predation on ambystomatid salamander eggs and larvae has been well documented (Duncan 2005. Herpetol. Rev. 36:294; Petranka 1998. Salamanders of the United States and Canada. Smithsonian Institution Press, Washington, DC. 587 pp.; Spohr 2005. Herpetol. Rev. 36:294), reports of predation on adults seem to be scarce. Frequently, either the predator or prey is left unidentified to species. For example, Bent (1938. Life Histories of North American Birds of Prey. USNM Bull. 170) records "salamanders" as part of the diet of the Northern Barred Owl (*Strix varia varia*) and Wilson (1938. Auk 55:187–197) is no more specific than "amphibians" when listing the food of this predator. Conversely, Petranka (1998, *op. cit.*) notes that "owls...snakes.... and other woodland predators" must prey upon *Ambystoma opacum*. Petranka (1998, *op. cit.*) cites but a single case in nature of adult *A. maculatum* being preyed upon; Raccoons (*Procyon lotor*) were recorded consuming three adults around a breeding site in Tennessee.

Here we report several cases of predation by the Barred Owl on adult *A. maculatum*. On 15 Oct 2011 at Hillsborough, Albert Co., New Brunswick, Canada (45.922°N, 64.642°W) a 782.3 g female owl was found fresh-dead on a roadway, presumably struck by an automobile. In the course of preparing the specimen for addition to the New Brunswick Museum bird collection (NBM 11768), the stomach was found to contain a whole, adult female *A. maculatum* 166.7 mm total length (estimated, tip of tail missing) and 24.0 g. Also, one of us (BF) has monitored Barred Owl nests in the Wolfville area of Kings Co., Nova Scotia (45.085°N, 64.343°W) from 1984 to the present. On four occasions among the 9–15 nests checked once annually during the first week of owl eggs hatching (~1–15 May), 1–2 adult *A. maculatum* have been encountered in nests. Both whole intact salamanders and salamander tails were observed, demonstrating (with the October record above) that *A. maculatum* is not only predated, but also consumed by *Strix varia*. This is in spite of the well-known noxious skin secretions and warning coloration of *A. maculatum* that are apparently effective at repelling many predators (Petranka 1998, *op. cit.*).

The observations above and other evidence suggest that amphibians may be more frequent (albeit a minor component) in the diet of the Barred Owl than other northeastern North American owl species. Snyder and Wiley (1976. Ornithological Monographs 20) summarize the diet of North American owls and report that lower vertebrates (fish, amphibians, and reptiles) make up 2.5% of this species' diet; among North American forest owls only the Pygmy Owl (*Glaucidium californicum*) and the Hawk Owl (*Surnia ulula*) take an equivalent percentage of lower vertebrates. Likewise, Bowsakowski and Smith (1992. Can. J. Zool. 70:984–992) found that among eastern forest owls only the Barred Owl fed on amphibians.

Adult *A. maculatum* live a mainly fossorial existence, emerging for about two weeks during a short breeding season in the early spring, although they may be found wandering about the forest floor on rainy nights in spring, summer, or autumn (Gilhen 1984. Amphibians and Reptiles of Nova Scotia. Nova Scotia Museum, Halifax. 162 pp.). During night-time overland migration to and from vernal pools or other wanderings, adult *A. maculatum* are clearly vulnerable to nocturnal predators such as the Barred Owl; it is also perhaps noteworthy that the breeding season for

A. maculatum in eastern Canada (late March to mid May; Gilhen 1984, *op. cit.*) coincides with the period when Barred Owl chicks may be in the nest (Karalus and Eckert 1974. The Owls of North America. Doubleday and Co., New York. 278 pp.)

***AMBYSTOMA MACULATUM* (Spotted Salamander). REPRODUCTION.** The Spotted Salamander is a wide-ranging salamander of the eastern United States that typically breeds in winter or early spring in ephemeral pools in lowland forests. *Ambystoma maculatum* is known to deposit 2–4 egg masses per year, each containing 1–250 eggs (Bishop 1941. New York State Mus. Bull. 324:1–365; Shoop 1974. Ecology 55:440–444). A positive relationship between SVL of the female and clutch size (i.e., full complement of eggs produced in a season) has been documented (Kaplan and Salthe 1979. Amer. Nat. 113:671–689; Wilbur 1977. Amer. Nat. 111:43–68), though Woodward (1982. Copeia 1982:157–160) states this relationship existed at only one of his two sites. Conversely, Shoop (1974, *op. cit.*) determined that adult female size was not a reliable index of clutch size. It is not known if a positive relationship exists between the SVL of a female and the number of embryos in her egg masses. In most studies, unless determined through direct observations in the field or genetics, the female responsible for a particular egg mass is unknown (Karraker and Gibbs 2011. Hydrobiologia 664:213–218). We have determined by chance the female responsible for five egg masses in our population through a novel means.

As part of ongoing research into the ecology and reproductive biology of Spotted Salamanders in the Kisatchie District of Kisatchie National Forest in Natchitoches Parish, Louisiana, USA, we have been counting the number of embryos per egg mass. We accomplish this by taking a digital photo of an egg mass as it is pressed gently between two clear plastic trays in a technique similar to Harris (1980. Copeia 1980:719–722), but where the bottom tray is marked with black lines 1 cm apart and then spray painted white to aid in counting embryos in the photograph (Fig. 1).

On 26 Jan 2012, we checked minnow traps that were set the previous evening to catch adult salamanders. We captured seven female *A. maculatum* in a small pool, six of which were still gravid. We took standard measurements, including SVL, and then implanted a Passive Integrated Transponder (PIT tag) into each adult female as was the protocol. About an hour after processing these animals we marked new *A. maculatum* egg masses found in the same small pool using PVC pin flags pushed carefully through the outer jelly. We did not have enough time to process them that evening, and it was not until a few days later on 1 Feb that we photographed those masses. We discovered that one of the masses flagged on 26 Jan contained a PIT tag in the outer jelly that corresponded to one of the six gravid females that were marked that same evening (Fig. 1). Therefore, the mass was laid within an hour after releasing the individual on 26 Jan in the daytime hours. On 1 Feb we again flagged new egg masses in the small pool and photographed these masses later on 8 Feb. Four of the masses flagged on 1 Feb and counted on 8 Feb contained PIT tags that corresponded to four of the remaining five gravid females captured in minnow traps in the small pool and tagged on 26 Jan.

A linear regression model indicated a significant positive relationship between the SVL of the female and the number of embryos per egg mass (Fig. 2, $R^2 = 0.85$, $p < 0.05$). The model shows an increase of 3.5 embryos per egg mass for every one millimeter of increased SVL. This result may seem intuitive as we know that larger females tend to have higher overall clutches (Kaplan and Salthe 1979, *op. cit.*; Wilbur 1977, *op. cit.*), but because this species typically lays multiple egg masses, the increased clutch size commonly observed in larger females may be represented by a greater number of embryos per mass as seen in this small sample, or alternatively, by laying an additional mass or two with the number of embryos per mass similar to smaller-bodied females.

To our knowledge, this is the first report of PIT tags being the means, albeit coincidentally, by which a particular egg mass of *Ambystoma maculatum* has been assigned to a particular female. Though we did retrieve PIT tags in egg masses from five of the six gravid females implanted, we are uncertain of the reliability

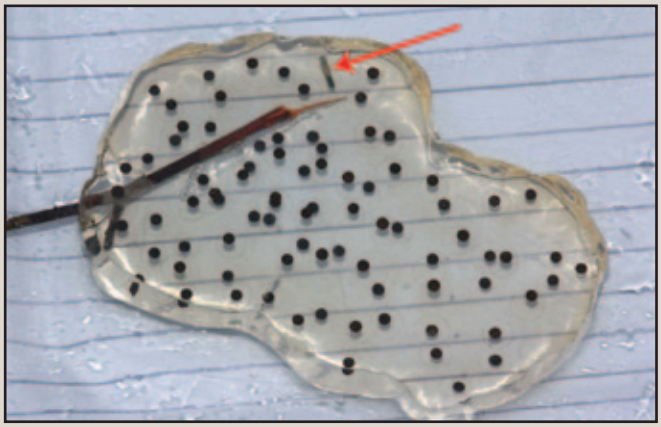

FIG. 1. An *Ambystoma maculatum* egg mass from Kisatchie National Forest, Natchitoches Parish, Louisiana, with a passive integrated transponder (PIT) tag laid with embryos in the outer jelly (top middle).

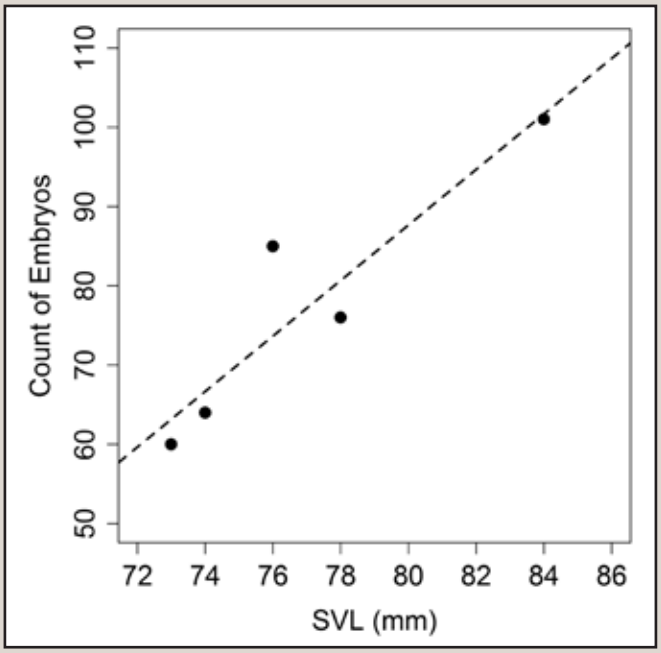

FIG. 2. The number of embryos per egg mass by snout–vent length (SVL) of female *Ambystoma maculatum.*

and safety of this technique to further elucidate the relationship between female body size and egg mass size. Besides potential harmful effects to the female or her clutch, only one egg mass would contain a PIT tag, and there may be considerable variation among multiple egg masses laid by the same female. For our purposes, losing the PIT tag from the adult female is counter to the goals of our study of this population, and we will no longer be implanting PIT tags into gravid females.

We thank the U.S. Forest Service for access and permitting to work in the Kisatchie National Forest. This research is financially supported by the U.S. Geological Survey's Amphibian Research and Monitoring Initiative (ARMI).

***AMBYSTOMA TEXANUM* (Small-mouthed Salamander). MOVEMENT.** Understanding the amount of terrestrial habitat used by pond-breeding amphibians is critically important for their conservation (Semlitsch and Bodie 2003. Cons. Biol. 17:1219–1228). Reports on how far adult *Ambystoma texanum* move in terrestrial habitat are limited (Petranka 1998. Salamanders of the United States and Canada. Smithsonian Institution Press, Washington, DC. 587 pp.). To date there are only two studies reporting movement distances of this species based on a total of 15 marked individuals. On an island in southern Illinois, *A. texanum* was found to have moved a maximum distance of 19.7 m between terrestrial cover objects (N = 5; Parmelee 1993. Univ. Kansas Mus. Nat. Hist. Occ. Pap. 160:1–33), and in southern Indiana, the range of distances *A. texanum* moved away from a breeding pond was 0–125 m, with an average of 52.4 m traveled (N = 10; Williams 1973. Ph.D. dissertation. Indiana University, Bloomington, Indiana. 47 pp.). Here we report an account of *A. texanum* movement in northeast Ohio.

As part of an ongoing monitoring project in Cuyahoga Co., Ohio, USA (41.55937°N, 81.59275°W; WGS84), from 16 to 24 March 2011 adult *A. texanum* were captured in funnel traps placed in breeding ponds, marked with visible implant elastomer (VIE) and then released. While opportunistically searching terrestrial cover objects at the study site on 20 April 2011, a VIE-marked adult female *A. texanum* was captured under a small log 58 m from the breeding pond where it was originally marked. Our finding is comparable to the average movement found by Williams (1973, *op. cit.*), but over twice as large as that found by Parmelee (1993, *op. cit.*). This account will add to the number of documented movements, as well as increases the number of geographic locations *A. texanum* movement has been observed.

This research was funded in part by the Northeastern Ohio Regional Sewer District. We thank Robin Halperin and Joseph Loucek for logistical assistance.

***PLETHODON JORDANI* (Jordan's Salamander). NEST GUARDING.** Very little is known about the eggs and young of *Plethodon jordani*, a species endemic to the Great Smoky Mountains National Park, USA. Egg clutches have never been reported, but it has been conjectured that females oviposit underground in late spring or early summer and that hatchlings emerge in late summer or fall (Petranka 1998. Salamanders of the United States and Canada. Smithsonian Institution Press, Washington, DC. 587 pp.; Beane et al. 2010. Amphibians and Reptiles of the Carolinas and Virginia, 2nd ed. Univ. North Carolina Press, Chapel Hill, North Carolina. 288 pp.).

At 1045 h on 19 Jun 2010, I flipped a piece of decaying bark on the north side of the Appalachian Trail, Cocke Co., Tennessee, USA (35.72166°N, 83.24580°W) and observed an adult *P. jordani* with its body encircling a clutch of eggs. The adult quickly fled into a hole in the substrate. I counted at least 17 eggs in the clutch. Eggs were translucent, creamy white in color, and in a thin gelatinous mass (Fig. 1A). A second clutch that contained at least 25 eggs was observed under a similar sized piece of moss-covered bark ca. 30 m away at the same site (Fig. 1B). I attribute these eggs to *P. jordani* because they were similar in size, shape, and color to the previous nest and because *P. jordani* is the most common salamander species at the site. Eight other adult *P. jordani* and one adult *Desmognathus wrighti* were also observed under pieces of bark and decaying logs at the site. The habitat is comprised of spruce-fir forest with a substrate of moist needles.

This note is the first known record and description of *P. jordani* eggs. In addition, this species has never been observed to guard nests, though other *Plethodon* species (e.g., *P. cinereus*, *P.*

FIG. 1. A) Clutch of *Plethodon jordani* eggs found under decaying bark on 19 Jun 2010. An adult was observed encircling the clutch. B) Second clutch of eggs found under moss-covered bark ca. 30 m from the clutch in (A), also attributed to *P. jordani*.

glutinosus) are known to exhibit this behavior (Highton and Savage 1961. Copeia 1961:95–98; Petranka 1998, *op cit.*).

ANURA — FROGS

***AGALYCHNIS CALLIDRYAS* (Red-eyed Tree Frog). VERTEBRATE DISPERSAL.** Effective dispersal via hitchhiking on vertebrates has been described for a number of plant and animal species. For example, some seeds have modified structures to grab onto fur, feathers, or socks of passing vertebrates (Sorensen 1986. Ann. Rev. Ecol. Syst. 17:443–463). Some species of flower mites (family Ascidae) are known to hitch rides between flowers in the nostril of hummingbirds (Colwell 1973. Am. Nat. 107:737–760). Despite the fact that vertebrate dispersal of organisms is common in nature, we were surprised to observe *Agalychnis callidryas* riding on the backs of Collared Peccaries (*Pecari tajacu*, Tayassuidae) at the Organization for Tropical Biology's La Selva Biological Station in Heredia Province, Costa Rica. On three independent occasions in different years researchers have observed *A. callidryas* riding on the backs of peccaries. Additionally, on one other occasion *A. callidryas* jumped onto the boot of a passing researcher and was carried for > 300 m, and could not be dislodged even by vigorous shaking of the leg. Because *A. callidryas* tadpoles must have access to standing water in ponds or swamps (Warkentin 2002. Physiol. Biochem. Zool. 75:155–164), and because peccaries often use low-lying swampy areas for mud bathing, contact between *A. callidryas* and peccaries could be relatively common.

The first observation of *A. callidryas* riding on a peccary was thought to be a fluke incident, and was fuel for much dinner discussion. After the three subsequent observations of *A. callidryas* riding on mammals, however, it appears frogs might use vertebrates as agents of dispersal more often than was previously appreciated. Interestingly, ours is not the first account of a frog riding on the back of a mammal. In 2007, Harry Greene provided an account of a *Leptodactylus chaquensis* riding on the back of a Capybara (*Hydrochoerus hydrochaeris*, Caviidae) in Brazil at the American Society of Ichthyologists and Herpetologists meeting (Donnelly 2008. Copeia 2008[1]:248–255).

***ANAXYRUS PUNCTATUS* (Red-spotted Toad). PREDATION.** On 18 May 2012 at 2155 h an adult male *Anaxyrus punctatus* was found being subdued by a Giant Water Bug (*Lethocerus uhleri*) at a permanent spring in the northern Chihuahuan Desert. The site is characterized by Chihuahuan Desert scrub and is located in the western versant of the Indio Mountains Research Station (IMRS; 30.797215°N, 105.011220°W, WGS84; 1269 m elev.) in Hudspeth Co., Texas, USA. At the time of the observation, the water bug was immobilizing the prey by grasping it securely on either side of the body with its first pair of legs and injecting powerful enzymes into the lateral portion (Fig. 1). Although the toad made spasmodic movements for a few seconds to attempt to rid itself of the predator and come to the surface for air, it did not succeed and remained stationary during most of the time we observed it. When we returned to the spring ca. 25 minutes later, we found the toad already dead and the belostomatid still feeding on it. Rainstorms that had previously occurred in the area likely stimulated the gathering of adult male *A. anaxyrus* to call and mate at the spring, consequently allowing them to be susceptible to adult belostomatids (N = 8) present in the water. Giant Water Bugs grasp their prey and inject toxic saliva and eventually suck all the liquid contents from their prey (Schuh and Slater 1995. True Bugs of the World [Hemiptera: Heteroptera]: Classification and Natural History. Cornell Univ. Press, Ithaca, New York. 416 pp.). Observations of predation by Giant Water Bugs have been reported for several species of amphibians (Toledo 2005. Herpetol. Rev. 36:395–400, and citations therein). In addition to the observation reported herein, adult *A. punctatus* had been previously reported to be prey of the belostomatid *L. angustipes* in Baja California Sur, Mexico (Luja et al. 2008. Herpetol. Rev. 39:75–76). To the best of our knowledge, the observation reported herein represents the first record of predation of *A. punctatus* by *L. uhleri*.

FIG. 1. An adult male Red-spotted Toad, *Anaxyrus punctatus*, being preyed upon by a Giant Water Bug, *Lethocerus uhleri* at Indio Mountains Research Station, Hudspeth County, Texas, USA.

We thank J. Alva, G. Wiseman, C. Anderson, K. Anderson, and the Maymester 2012 field biology class for their company in the field.

***AUBRIA SUBSIGILLATA* (Brown Ball Frog). PARENTAL CARE.** *Aubria subsigillata* is a large frog that lives and breeds in still-water pools and swamps adjacent to streams and rivers in forested West and Central Africa (Rodel et al. 2005. Salamandra 41:107–127). Schiøtz (1963. The Amphibians of Nigeria. Vidensk. Medd. Fra Dansk naturh. Foren 125:1–92) reported schooling behavior for *A. subsigillata* larvae similar to *Aubria*'s sister taxon, *Pyxicephalus*. Based on this schooling behavior, Ohler and Kazadi (1990. Alytes 8:25–40) hypothesized that parental care exists

in *Aubria* similar to what is well documented for *Pyxicephalus adspersus* (Poynton and Broadley 1985. Ann. Natal Mus. 27:115–181). Yet, parental care has not been confirmed for any species of *Aubria*. During a trip to Gabon in 2011, we observed evidence for parental care by *A. subsigillata* on two occasions, each in a different national park. On both occasions, an adult was seen partially submerged in the water near a tight cluster of tadpoles (approx. 35 larvae). The first individual was observed 9 Feb 2011 at 0020 h in a shallow forested pool near the coast in Pongara National Park, northwestern Gabon (00.34293°N, 009.34470°E; 7 m elev.). The tadpoles were small (total length ca. 17 mm). The second individual was observed in a similarly shallow forested pool next to a river in Batéké National Park in southeastern Gabon (01.97626°S, 014.00377°E; 401 m elev.) on 3 March 2011 at 1345 h. The tadpoles at this site were larger (ca. 40 mm) than at Pongara suggesting some degree of extended parental care. Each time we approached the individual guarding a school of tadpoles, it quickly retreated under leaves at the bottom of the pool. In Pongara NP, we returned to the pool 30 min after the initial encounter and found the individual positioned back near the school of tadpoles. In Batéké NP, we returned to the same site on three occasions (35 min, 47 h 30 min, and 48 h 10 min after initial encounter), and each time we found the adult positioned near the cluster of tadpoles. Given the skittish behavior we observed in the adults each time they were approached, along with their readiness to return to their tadpoles, we suspect the adult is defending the tadpoles against predators, such as fish or possibly other *A. subsigillata*, as cannibalism has been reported for this species (Knoepffler 1976. Zool. Africana 11[2]:369–371).

***BUFO MARINUS* (Cane Toad). PREDATION.** *Bufo marinus* was introduced into the Solomon Islands in the 1930s as a biological control for cane beetles and mosquitoes. Since then the species has become the most widespread invasive frog in the archipelago (Pikacha et al. 2008. Frogs of the Solomon Islands. Instit. Applied Sci., Univ. South Pacific. 68 pp.) and is even found on very small islands, and in submontane forests on the large islands (PP, pers. obs.). Outside of its native range a review of invertebrate predators include meat ants (*Iridomyrmex* sp), freshwater crayfish (*Cherax* spp., as *Euastacus hystricosus*, *E. suttoni*, and *E. valentulus*), crabs, beetles, and snails (Crossland and Alford 1998 Austral. J. Ecol. 23:129–137; Shine 2010. Quart. Rev. Biol. 85[3]:253–291; Ward-Fear et al. 2009. Funct. Ecol. 23[3]:559–568). All records have been from Australian studies, but very little has been reported from Pacific islands like the Solomon Islands.

In this paper we report our observations of predation by the Giant Australasian Centipede (*Ethmostigmus rubripes*) on *B. marinus* during field surveys on Guadalcanal, Solomon Islands. The initial observation was made on the night of 12 Dec 2010 in lowland forests, along the Tina River (9.59395°S, 160.0310333°E). We first spotted the centipede dragging the *B. marinus* at 2110 h along the forest floor before moving a meter from the original location where it climbed up an *Alpinia pupurata* ginger (Fig. 1). The centipede started eating the soft tissue on the underside of the *B. marinus*, first digging into the stomach contents, abdomen, skin, and side of jaw. By 2155 h it had made its way to the tip of the mouth, and by 2157 h feeding into the eye socket and lip. By 2200 h it was eating the soft underside of the jaw.

The vegetation here was riparian in a typical lowland forest type, dominated by *Broussonetia papyrifera*, *Macaranga*

COLOR REPRODUCTION SUPPORTED BY THE THOMAS BEAUVAIS FUND PHOTO BY P. PIKACHA

FIG. 1. An adult Giant Australasian Centipede (*Ethmostigmus rubripes*) preying on a subadult Cane Toad (*Bufo marinus*) on Guadalcanal, Solomon Islands.

tanarius, *Kleinhovia hospita*, *Alpinia oceanica*, *Leea indica*, and *Dendrocnide salomonense*. Various shrubs and herbaceous plants occupy the forest floor and understory canopy. Tall canopy cover was occupied by *Pometia pinnata*, *Alstonia scholaris*, and *Vitex cofassus* trees. There was evidence of forest disturbance with secondary trees, and camping and hunting remnants within the area.

After we observed the centipede predation on the toad, we further counted more than 10 *B. marinus* within close proximity to our initial observation site on the bank of the Tina River. Here we noted two more Giant Australasian Centipedes, both of which were dead. Upon close inspection, there were no lesions, abrasions, or damage to the centipedes' bodies to suggest attack by larger predators. We suspect that these centipedes had very recently killed and ingested Cane Toads and subsequently succumbed to the toads' toxins.

PATRICK PIKACHA, Solomon Islands Community Conservation Partnership, Honiara, Solomon Islands, and University of Queensland, Faculty of Agriculture and Science, Gatton Campus, Australia (e-mail: patrick.pikacha@gmail.com); **MYKNEE SIRIKOLO**, Solomon Islands Community Conservation Partnership, Honiara, Solomon Islands (e-mail: mykneesirikolo@gmail.com).

***CHIROMANTIS VITTATUS* (Two-striped Pigmy Tree Frog). PARENTAL CARE.** *Chiromantis vittatus* is distributed in southern China, India, Laos, Myanmar, Thailand, and Vietnam. It has been reported that the congener *C. hansenae* of Thailand exhibits parental care that may enhance survival rates of eggs (Sheridan and Ocock 2008. Copeia 2008:733–736). Here we report the first documented observation of parental care exhibited by *C. vittatus* in the wild.

During a field survey at Bawangling National Nature Reserve, Hainan Island, China on 9 August 2010, at 2030 h we detected two

COLOR REPRODUCTION SUPPORTED BY THE THOMAS BEAUVAIS FUND

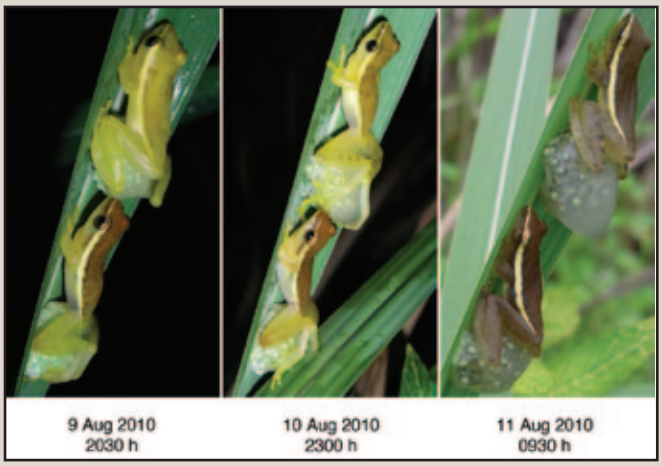

FIG. 1. Two adult *Chiromantis vittatus* covering egg masses on three consecutive days, Bawangling National Nature Reserve, Hainan Island, China.

unsexed *C. vittatus* each attending an egg mass. The egg masses were attached, positioned closely together, on the underside of a leaf of the grass *Miscanthus*, ca. 70 cm above ground, hanging above an ephemeral pond (19.11798°N, 109.10446°E, WGS84; elev. 350 m). The adults covered the egg masses with their posterior abdomen and hind legs (Fig. 1). On the next two consecutive days, we observed the adults attending these two egg masses at 2300 h (10 August 2010) and 0930 h (11 August 2010), suggesting they attended the egg masses continuously. It was evident that this species exhibits parental care by egg attending. The canopy cover of the site was about 20% so that the egg masses could be exposed to direct sunlight; daytime egg covering may help maintain the moisture level of the egg masses whereas nocturnal egg attending may help prevent fly infestation and fungal infection (Sheridan and Ocock 2008, *op. cit.*). It has been suggested that *C. hansenae* is a junior synonym of *C. vittatus* (Wilkinson et al. 2003. Proc. California Acad. Sci. 54:17–26), and our observation confirms the similarity of the unusual reproductive behavior of these two taxa.

CHAN** (e-mail: boscokf@kfbg.org) and **GANG LU** (e-mail: lugang@kfbg.org), Kadoorie Conservation China, Kadoorie Farm and Botanic Garden, Lam Kam Road, Tai Po, New Territories, Hong Kong SAR, P.R. China.

***COCHRANELLA GRANULOSA* (Granular Glass Frog). FEEDING BEHAVIOR.** Scarce information is available concerning the behavior and habits of juvenile and non-reproductive glass frogs in the wild, as most observations have been taken on calling males (Kubicki 2007. Glass Frogs of Costa Rica. INBio. Heredia, Costa Rica. 299 pp.*)* *Cochranella granulosa* is a medium to large nocturnal centrolenid frog that is common in the humid forests of Costa Rica (Savage 2002. The Amphibians and Reptiles of Costa Rica: A Herpetofauna between Two Continents, between Two Seas. Univ. Chicago Press, Chicago, Illinois. 934 pp.). This species is mostly observed along streams with little or no alteration but also occurs in streams associated with agricultural areas (Kubicki 2007, *op. cit.*). Like most species of this family, little is known regarding its ecology. On 24 June 2011, at 2215 h, we were surveying and monitoring the herpetofauna of a seasonal swamp located in The Osa Biodiversity Center at Río Piro, Península de Osa, Costa Rica (8.2478°N, 83.2024°W; WGS 84). There, we observed an adult male *C. granulosa* on the ground, feeding on small arthropods. We also documented the presence of common swamp-breeding species such as *Engystomops pustulosus* and *Leptodactylus fragilis*. The frog was collected and deposited at the Museo de Zoología, Universidad de Costa Rica (UCR21242). To our knowledge, this is the first case of a centrolenid frog feeding in a swamp. This species seems to use a wider variety of habitats compared to other glass frogs. The species has also been observed reproducing in a small pond in a humid forest (Kubicki 2007, *op. cit.*).

We thank Bryan Kubicki and Jonathan Losos for comments on this note.

HÉCTOR ZUMBADO-ULATE, Escuela de Biología, Universidad de Costa Rica, Sede Rodrigo Facio, San Pedro, Costa Rica; Asociación para la Conservación y el Estudio de la Biodiversidad, San Pedro, Costa Rica (hugozu1@yahoo.com); **VÍCTOR ACOSTA-CHAVES,** Escuela de Biología, Universidad de Costa Rica, Sede Rodrigo Facio, San Pedro, Costa Rica (e-mail: victor.acosta@ucr.ac.cr).

***ELEUTHERODACTYLUS ZEUS* (Cuban Giant Frog). RECORD SIZE.** *Eleutherodactylus zeus* is an endemic Cuban frog of the subgenus *Syrrophus* (Hedges et al. 2008. Zootaxa 1737:1–182). This species is only known from the Cordillera de Guaniguanico, in Western Cuba and occurs in mesic broadleaf forest on a limestone base (Schwartz and Henderson 1991. Amphibians and Reptiles of the West Indies: Descriptions, Distributions, and Natural History. Univ. Florida Press, Gainsville. 714 pp.). It is saxicolous or clivicolous, always associated with limestone, and not recorded outside of forest habitats (Henderson and Powell 2009. Natural History of West Indies Reptiles and Amphibians. Univ. Florida Press, Gainsville. 945 pp.).

During a herpetological expedition to El Moncada, Viñales, Pinar del Río, during April 2012, a very large adult female *Eleutherodactylus zeus* (127.4 mm SVL) was sighted inside of the Santo Tomás Cavern, Sierra de Quemados (22.544496°N, 83.846895°W). This individual was found on the soil in total darkness, 20 m from the entrance of the cave at 1620 h, with 23.2°C air temperature and 87% relative humidity (Termohygrometer HANNA Instruments Hi 9565; ± 5% RH, ± 0.5°C). The voucher specimen was preserved in 70% ethanol, verified by R. Alonso and deposited in the Zoological Collection of the Natural History Museum of Pinar del Río province, Cuba (field number LYG-387).

Previously, Schwartz (1958. Proc. Biol. Soc. Washington 71:37–42) found that the large females of this species did not exceed the 90 mm SVL. Díaz and Cádiz (2008. ABC Taxa 4:1–294) reported an individual 123.2 mm SVL. To our knowledge, this new measurement constitutes a record size and reaffirms that *E. zeus* as the largest species in the Eleutherodactylidae from the West Indies.

I thank I. T. Carrasco (Neneso) and Y. R. Cabrera for help during field work, and R. Alonso for verification of the species and comments on the manuscript. The National Speleological Training Center (CNEE) provided hospitality and logistical support.

L. YUSNAVIEL GARCÍA, Centro de Investigaciones y Servicios Ambientales ECOVIDA, km 2½ carretera a Luis Lazo, Pinar del Río, Cuba, CP: 20 300; e-mail: chispa@ecovida.vega.inf.cu.

***HYLARANA PICTURATA* (Spotted Stream Frog). HABITAT.** *Hylarana picturata* is a moderate-sized anuran (to 70 mm SVL) with unmistakable coloration of black back and sides marked with blotches and lined with yellow orange or orange red stripes

from the snout up to along both upper eyelids (Das 2007. A Pocket Guide: Amphibians and Reptiles of Brunei. Natural History Publications [Borneo] Sdn. Bhd. Kota Kinabalu. viii + 200 pp.; Inger and Stuebing 2005. A Field Guide to the Frogs of Borneo. 2nd ed. Natural History Publications [Borneo] Sdn. Bhd. Kota Kinabalu. viii + 201 pp.; Malkmus et al. 2002. Amphibians and Reptiles of Mount Kinabalu [North Borneo]. A.R.G. Gantner Verlag K.G. Ruggell. 424 pp.). *Hylarana picturata* has been recorded in Peninsular Thailand (Das 2007, *op. cit.*), Peninsular Malaysia (Chan et al. 2010. Russian J. Herpetol. 17[3]:202–206), Sumatra (Inger et al. 2004. *Hylarana picturata*. IUCN 2011. IUCN Red List of Threatened Species. Version 2011.2. <www.iucnredlist.org>. Accessed 9 May 2012; Inger and Stuebing 2005, *op. cit.*), throughout Borneo (Frost 2011. Amphibian Species of the World: an Online Reference. Version 5.5 [31 January 2011]. Electronic database http://research.amnh.org/vz/herpetology/amphibia/. American Museum of Natural History, New York. Accessed 9 May 2012), and the Philippines (Malkmus et al. 2002, *op. cit.*). The species dwells in primary and old secondary forests from near sea level to below 1000 m elev. (Inger et al. 2004, *op. cit.*), and is closely associated with streams (Brown and Guttman 2002. Biol. J. Linn. Soc. 76:393–461; Keller et al. 2009. J. Anim. Ecol. 78[2]:305–314; Haas and Das 2012. Frogs of Borneo – The Frogs of East Malaysia and their Larval Forms: an Online Photographic Guide. Version 1.1.1. [4 May 2012]. http://www.frogsofborneo.org. Zoological Museum Hamburg, Germany. Accessed 9 May 2012; Sheridan et al. 2012. Tropical Natural History 12[1]:1–8) as the adults breed and tadpoles develop in leaf drifts in streams before the juveniles move away to live on the forest floor until reaching maturity (ca. 25 mm SVL) and permanently return to the streams (Inger and Stuebing 2005, *op. cit.*). Herein we report the first occurrence of mature *H. picturata* away from a stream in Malaysia.

On 10 April 2012 at 2204 h, a female *H. picturata* (61 mm SVL, 14.4 g) was sampled from among unused timber within the compound of Gunung (= mountain) Kuli Research Station (5.027°N, 117.048°E; 320 m elev.), Imbak Canyon Conservation Area, Tongod District, Sandakan Division, Sabah, Bornean Malaysia. Air temperature was 20.5°C. The individual was found 40 m from the nearest running water, Sungai (= river) Kuli, which is a shallow, rocky-bottomed torrential stream with calmer side sections. The stream has an average width of 11.8 m and average depth of 115.9 mm. The pH for the stream water was 6.67. Another adult female *H. picturata* (53 mm SVL, 11.7g) was sampled 12 April 2012 at 2250 h within the compound of the research station but from the base of a tree stump 80 m from Sungai Kuli. Air temperature was 20.9°C. The occurrence of the two individuals omits the causal factor of randomness or attempted escape from predation. No potential predators were observed throughout the duration of our fieldwork at the station. In fact, the research station houses several other forest and forest-edge anurans: *Chaperina fusca*, *Polypedates macrotis*, *P. otilophus*, and *Staurois latopalmatus*, in addition to the human commensal species: *Fejervarya limnocharis*, and *Polypedates leucomystax*. This finding is imperative to augment the natural history understanding of *H. picturata* to avoid sampling efforts of the species that only concentrate on riparian habitats for its adults, and may result in a false impression of its absence from localities. Such false information influences conservation strategies for the species. In accordance to the requirement of the management of Imbak Canyon Conservation Area, the two *H. picturata* were released on site after taking measurements and photographs. The photographic vouchers (10 April 2012: ICCA_Anuran_0089_2012, and 12 April 2012: ICCA_Anuran_0210_2012) are available from the first author.

We are grateful to Helpis Ismail, Simon Kuyun, Johnny Gisil, and Stevson Justin Adeh for their assistance during the fieldwork at Gunung Kuli Research Station, Imbak Canyon Conservation Area. We thank the Institute for Tropical Biology and Conservation, Universiti Malaysia Sabah, and Sabah Foundation for support.

***HYPOPACHUS VARIOLOSUS* (Sheep Frog). DIET.** *Hypopachus variolosus* is distributed on the Pacific versant of Mexico, and the Atlantic versant from southern Texas to Costa Rica (Dixon and Lemos-Espinal 2010. Amphibians and Reptiles of the State of Querétaro, Mexico. Texas A&M University, UNAM and CONABIO, México, D.F. 428 pp.). Its diet has been reported to consist of invertebrates, especially ants and termites (Lee 2000. A Field Guide to the Amphibians and Reptiles of the Maya World: the Lowlands of Mexico, Northern Guatemala, and Belize. Cornell Univ. Press, Ithaca, New York. 402 pp.), without specific information. Herein we report a specific termite as prey of *H. variolosus*.

On 18 Sept 2011, during fieldwork around the edge of a pond in the Municipality of Chapala, Jalisco, México (20.323975°N, 103.218219°W; 1791 m elev.), we found an adult *H. variolosus* (45 mm SVL) at 0109 h. The specimen was observed actively feeding on termites, which were collected and identified as *Tenuirostritermes incisus* (Snyder 1922) (Isoptera: Termitidae: Nasutitermitinae). Specimens are deposited at the Entomological Collection, Centro de Estudios en Zoología, CUCBA, Universidad de Guadalajara (CZUG).

We thank Rudolf H. Scheffrahn for identification of termites, and Fidel Rodriguez-Ramirez and J. de J. Ascencio-Arrayga for field assistance. JLB-R was supported by a CONACYT Scholarship for his Master's degree in development.

JOSÉ LUIS BARRAGÁN-RAMÍREZ (e-mail: barragan5478@yahoo.com.mx) and **JOSÉ LUIS NAVARRETE-HEREDIA** (e-mail: glunusmx@gmail.com), Centro Universitario de Ciencias Biológicas y Agropecuarias (CUCBA), Universidad de Guadalajara, Carretera a Nogales Km. 15.5, La Agujas, Nextipac, Zapopan, Jalisco, México.

***HYPSIBOAS RANICEPS* (Chaco Treefrog). ENDOPARASITES.** *Hypsiboas raniceps* is a hylid frog widespread in South America (Frost 2011. Amphibian Species of the World: an Online Reference. Version 5.5 http://research.amnh.org/vz/herpetology/amphibia/). In Brazil, it has been found across the major biomes, such as the Cerrado, Caatinga, Atlantic Forest, and Amazon (Guimarães and Bastos 2003. Iheringia 93:149–158). Despite its huge distribution, several aspects of its natural history are lacking, such as parasitism. To the best of our knowledge, there are three helminths reported from *H. raniceps*: the nematodes

Aplectana hylambatis (McAllister et al. 2010. Comp. Parasitol. 77:184–201), and *Cosmocerca parva* (Gonzáles and Hamann 2011. Comp. Parasitol. 78:212–216), and the trematode *Glypthelmins vitellinophilum* (Dobbin Jr. 1957. Mem. Inst. Oswaldo Cruz 56:153–157). Herein, we report a new nematode parasitizing *H. raniceps* from the Brazilian state of Ceará. An adult female *H. raniceps* was collected on 17 Nov 2011, at Trilha Ecológica do Grangeiro (7.279722°S, 39.438055°W), Crato municipality, state of Ceará, Brazil. The specimen were euthanized and deposited into the Coleção Herpetológica da Universidade Regional do Cariri (URCA-H 258). We examined the body cavity, esophagus, stomach, lungs, and the small and large intestines under a stereomicroscope for helminths. Helminths were cleared in Hoyer's solution, identified, and deposited in the Coleção Parasitológica da Universidade Regional do Cariri (URCA-P 262). Three specimens of the nematode *Rhabdias pseudospherocephala* were found in the lungs. Species of *Rhabdias* have been reported in a variety of anurans, mainly in toads of the genus *Rhinella* (Vicente and Rodrigues 1991. Rev. Bras. Zool. 7:549–626). To date, there are few reports of *Rhabdias* spp. parasitizing hylid frogs in Brazil (Holmes et al. 2008. Parasitol. Res. 102:621–623). Our identification fits with the description of *R. pseudosphaerocephala* (Kuzmim et al. 2007. J. Parasitol. 93:159–165), although this nematode has been indicated as host specific to bufonids (Santos et al. 2011. Mem. Inst. Oswaldo Cruz 106:433–440). Thus, *H. raniceps* is a new host record and Ceará state a new locality record for *Rhabdias pseudospherocephala.*

***LITHOBATES CATESBEIANUS* (American Bullfrog). DIET.** The American Bullfrog is an aggressive competitor and generalist predator that is profoundly impacting ecological communities throughout its invasive range in the western United States (Nussbaum et al. 1983. Amphibians and Reptiles of the Pacific Northwest. Univ. Idaho Press, Moscow. 336 pp.). In Oregon, the American Bullfrog is implicated in the declines of several native species of conservation concern, including the Northern Red-legged Frog (*Rana aurora*), the Oregon Spotted Frog (*Rana pretiosa*), and the Western Pond Turtle (*Actinemys marmorata*) (Nussbaum et al. 1983, *op. cit.*). This is the first report that American Bullfrogs predate the Oregon Chub (*Oregonichthys crameri*), a threatened minnow endemic to the Willamette River basin of Oregon (Markle et al. 1991. Copeia 1991:277–293). Prior to this account, only anecdotal evidence for a predator-prey interaction between American Bullfrogs and Oregon Chub was available based on observations that the two species often occur syntopically in warm-water, off-channel habitats (Snyder 1908. Bull. U.S. Bur. Fish. 27:153–189). Scheerer (1999. Fish Research Project, Annual Progress Report EF-91 VII-1. Portland, Oregon. 24 pp.) and Scheerer and Apke (1998. Fish Research Project E96970022, Annual Progress Report. Corvallis, Oregon) previously noted that the largest chub populations were found at Willamette Valley basin sites devoid of bullfrogs, but subsequent diet analysis did not find evidence of bullfrog predation on chubs.

Our study site (44.4528°N, 123.3750°W) is a privately owned wetland located south of Corvallis, Oregon in the Beaver Creek drainage of the mainstem Willamette River. This wetland is part of a 30-acre restoration project initiated in 1992 consisting of three permanent ponds seasonally connected through flooding. The site is also unique in that it serves as prominent Oregon Chub reintroduction habitat under the Oregon Chub Recovery Plan (USFWS 1998. Recovery Plan for the Oregon Chub. Portland, Oregon. 86 pp.). A total of 573 Oregon Chub from three source populations (DeHaan et al. 2010. U.S. Fish and Wildlife Service, Abernathy Fish Technology Center. Final report) were introduced between 1997 and 1998 (USFWS 2010a. Fed. Reg. 75:11010–11067). Also inhabiting this site are Northern Red-legged Frogs (threatened), Western Pond Turtles (sensitive species), and invasive American Bullfrogs.

We collected six adult American Bullfrogs on 9 Aug 2011 via hook and line sampling as part of a regional study on invasive species community dynamics. We euthanized the animals following standard protocol and recorded measurements for weight, snout–vent length, and sex. Stomachs were excised and fixed in 95% ethanol for 36 h before contents were processed. Prey items were flushed with dechlorinated water and observed with a dissecting microscope to aid in identification to the lowest possible taxon. We aggregated contents to taxonomic order and assigned values of absolute and relative abundance (total count; N and N%) and frequency (number of stomachs containing item; F and F%), as well as occurrence (percentage of 6 stomachs containing item; 0%) (Table 1).

A total of 30 prey items were found in the six stomachs, with orders Hemiptera and Coleoptera representing the greatest percentage of the diet (23.3% and 20%, respectively). Three Oregon Chub (order Cypriniformes) were found in 2 out of 6 stomachs (33.3%). Although some digestive decomposition had occurred to the three specimens, enough tissue and distinguishing morphological features had been preserved for positive identification by Oregon State University ichthyologist, Doug Markle. Other vertebrates present in the diet included juvenile American Bullfrogs which were found in one-third of stomachs constituting 10% of the total diet, and Northwestern Salamanders (*Ambystoma gracile*), which were found in one-third of the stomachs and represented 6.7% of the total diet.

Since the Oregon Chub's listing under the Endangered Species Act in 1993 (58 FR 53800; October 18, 1993), the species' conservation status has improved from endangered to threatened in part due to actions outlined in the Oregon Chub Recovery Plan

TABLE 1. Diet of six American Bullfrogs collected from wetland in Corvallis, Oregon, showing absolute and relative values of abundance (N and N%), frequency (F and F%), and occurrence (O%).

Prey Order	N	N%	F	F%	O%
Anura	3	10.0	2	8	33.3
Aranae	1	3.3	1	4	16.7

published in 1998 (USFWS 1998, *op. cit.*). Recovery strategies were enacted to reverse the decline of this species by protecting existing populations and designating critical habitat throughout its historic range (USFWS 1998, *op. cit.*; USFWS 2010b. Fed. Reg. 75:21179–21189). At the time of Oregon Chub reintroduction to our study site, threats to habitat integrity were identified as American Bullfrogs and agricultural runoff (USFWS 1998, *op. cit.*), although current management concerns are primarily over water quality (USFWS 2010). Our findings emphasize the importance of American Bullfrog removal and resistance strategies at chub reintroduction sites, especially since American Bullfrogs and chub have similar habitat requirements and frequently co-occur with other species of high conservation priority. Oregon Chub continue to face synergistic pressures from habitat loss and invasive species, so carefully planned reintroductions and persistent American Bullfrogs management will increase suitable habitat and aid in Oregon Chub population recovery.

Stomach contents were deposited in the laboratory in 174 Nash Hall, Corvallis, Oregon, 97331, USA. We extend our gratitude to Doug Markle and Joe Beatty for identifying stomach items, and to the members of our research lab at Oregon State University for their support during this study. We are also grateful for contributions from the Natural Resources Conservation Service and the Wetlands Reserve Program landowners who granted access to their wetland easements; without their help, this research would not have been possible.

JENNIFER C. ROWE (e-mail: jennifer.rowe@oregonstate.edu) and **TIFFANY S. GARCIA** (e-mail: tiffany.garcia@oregonstate.edu), Oregon State University, Department of Fisheries and Wildlife, 104 Nash Hall, Corvallis, Oregon 97331, USA.

***PHYLLOMEDUSA AZUREA*. MULTI-MALE SPAWNING.** Multimale spawning has been rarely documented for neotropical anurans (Prado and Haddad 2003. J. Herpetol. 37:354–362; Prado et al. 2006. Herpetol. Rev. 37:206–207). We observed a polyandrous mating in *Phyllomedusa azurea* in an open area of Cerrado, at Nioaque municipality (21.186109°S, 56.178786°W), Mato Grosso do Sul, western Brazil. On 20 Jan 2011, around 0800 h, the behavior was observed occurring early in the morning of a cloudy day. Two males tried to join a pair already in amplexus. The female was laying eggs in a leaf of grass (*Brachiaria* sp.), while two opportunistic males tried to position their cloacae close to the eggs that were being deposited (Fig. 1A). After more than two hours, the opportunistic males moved away from the site, one at a time; the male in amplexus also moved away. However, the leaf of *Brachiaria* sp. containing the clutch was left opened, exposing the eggs to sun radiation, wind, rain, and extreme variations in temperature and humidity (Fig. 2B). We did not monitor the clutch, however, we believe that it has been partially or almost totally desiccated. Probably this leaf was not closed due to the weight of three males on the female, which pulled it down, preventing the pair from sealing the leaf. A similar event was described for *P. distincta* in south Brazil (Prado et al. 2006, *op. cit.*). In that event, two males were trying to fertilize the eggs while the female was spawning and their weight disturbed the female, preventing her from sealing the leaf. Consequently, almost the entire clutch desiccated (Prado et al. 2006, *op. cit.*). The few cases of multiple amplexus reported for anurans may indicate that the costs involved are higher than the advantages (Lodé and Lesbarrères 2004. Naturwissenschaften 91:44–47). However, multimale spawning has been described for three congeneric species of *P. azurea* (Oliveira et al. 2012. J. Nat. Hist. 46:117–129; Prado et al. 2006, *op. cit.*; Wogel et al. 2005. J. Nat. Hist. 39:2035–2045), indicating that polyandrous mating may be more common than reported, at least for species in this genus (Roberts et al. 1999. Anim. Behav. 57:721–726). Mating with several males may be advantageous for females by potentially increasing fertilization success, providing better quality sperm, or increasing offspring genetic diversity (Prado et al. 2006, *op. cit.*). For the opportunistic males, polyandry may increase the chances of fertilizing at least some of the eggs (Roberts et al. 1999. Anim. Behav. 57:721–726). Further studies should focus on such aspects, to elucidate the possible advantages related to multimale spawning in anurans.

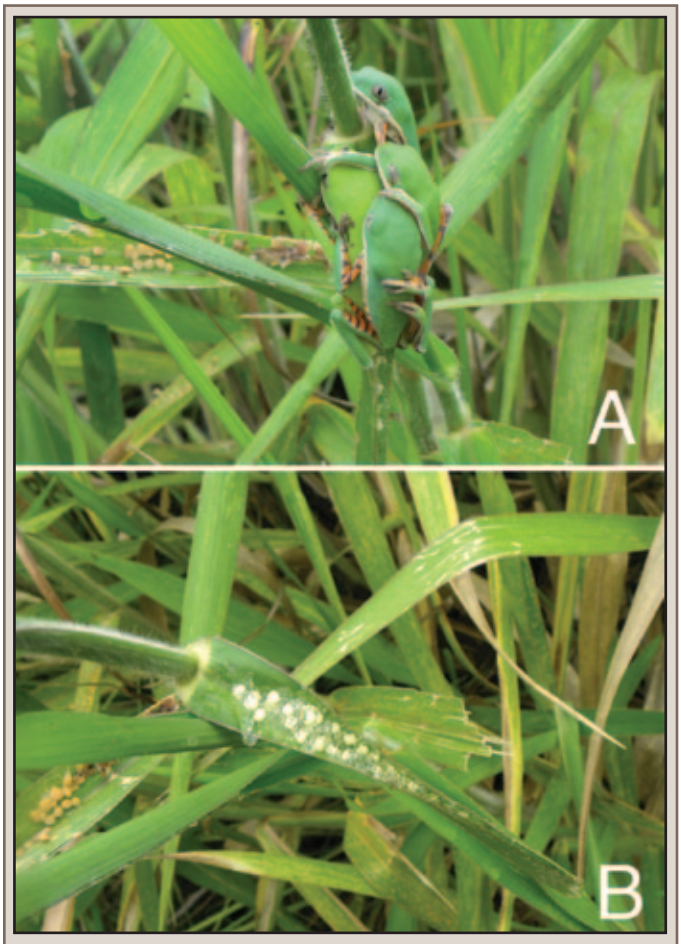

FIG. 1. Multimale spawning in *Phyllomedusa azurea*. A) One female of *Phyllomedusa azurea* with two opportunistic males in an open area of Cerrado, Brazil; B) Leaf of *Brachiaria* sp. exposing the clutch of *Phyllomedusa azurea* after the female and three males had left the site of oviposition in an open area of Cerrado, Brazil.

FIG. 1. Males of *Phyllomedusa nordestina* in physical attack.

***PHYLLOMEDUSA NORDESTINA* (Northeast Orange-Legged Leaf Frog). PHYSICAL ATTACK.** Sexual selection occurs when there is competition for sexual partners (scarce resource) causing differences in fitness among individuals in the same population (Wogel 2007. Pap. Avulsos Zool. 47[13]:165–174). The territorial behavior combines acoustic interactions, attitudes, and struggles that are the result of male competition for calling sites, favorable spawning, and consequently females (Martins et al. 1998. Amphibia-Reptilia 19:65–73). Studies on agonistic behavior of *Phyllomedusa* show that males exhibit territorial behavior during the reproductive period (Abrunhosa and Wogel 2004. Amphibia-Reptilia 25:125–135), emitting territorial calls and getting into physical combat with the resident male (Costa et al. 2010. Phyllomedusa 9[2]:99–108; Wogel et al. 2004. Herpetol. Rev. 35[3]:239–243).

We observed an event with *Phyllomedusa nordestina* involving a dispute among three males (Fig. 1). This is the first record of physical attack in the genus *Phyllomedusa* in Caatinga. The event occurred on 24 April 2010 at 2038 h, in a temporary pond at Monumento Natural Grota do Angico, Poço Redondo, Sergipe (9.6638889°S, 37.6825000°W, 200 m elev., SAD69). Two males invaded the territory of the resident male emitting agonistic calls until they came into physical contact. Later, they were one above the other emitting advertisement calls. According to Vilaça et al. (2011. J. Nat. Hist. 45[29-20]:1823–1834) males of *P. nordestina* exhibit territorial behavior at vocalization sites, defending their territories through aggressive interactions or vocal activities.

The aggressive behavior of the genus *Phyllomedusa* can be considered a synapomorphy of the group, because it is similar among species and may result for similar reasons, such as disputes over territory or females (Abrunhosa and Wogel 2004, *op. cit.*; Costa et al. 2010, *op. cit.*; Wogel et al. 2004, *op. cit.*).

***PLEURODEMA GUAYAPAE*. EGG PREDATION.** Complex oviposition strategies of tropical anurans, such as terrestrial oviposition or foam nests, are believed to be a fixed trait as a means to limit exposure to aquatic egg predators (Magnusson and Hero 1991. Oecologica 86:310–318). The floating foam nests constructed by the anurans of the family Leiuperidae are one such oviposition strategy that protects their eggs from predators as well as desiccation (Wells 2007. The Ecology and Behavior of Amphibians. Univ. Chicago Press, Chicago, Illinois. 1148 pp.).

On 7 Feb 2011 at 0800 h I observed the foam nest of *Pleurodema guayapae* in an ephemeral pond (ca. 2 m^2) that had been formed during the previous night's rain in the Isoceño community of Kuaridenda, Cordillera Province, Santa Cruz Department, Bolivia (19.17°S, 62.53°W; WGS84). The nest had been blown to the edge of the pond by the wind, where upon closer examination I observed dozens of small red ants (Hymenoptera; Formicidae) swarming the exposed eggs that were in contact with the pond's edge. I returned to the pond at 1500 h to find that the entire nest had been depredated by the ants.

Pleurodema guayapae constructs flattened foam nests, depositing them in temporary ponds that form after heavy rainstorms (Cei 1980. Monitor. Zool. Ital. Monogr. 2:380–382). By eliminating contact with the water's surface, these nests may provide suitable protection against aquatic predators, such as the carnivorous tadpoles of *Ceratophrys cranwelli*, which commonly occur in temporary ponds in the area (pers. obs.). However, these foam nests do not envelop the eggs completely, and the eggs are often visible and exposed at the top of the nest (pers. obs.). Thus these nests may be inadequate in their protection against terrestrial predators (Schalk 2010. Herpetol. Rev. 41:202). *Pleurodema guayapae* may compensate for this increased vulnerability to egg predators with a shortened egg life stage (Johnson et al. 2003. Can. J. Zool. 81:1608–1613), which could be explored further though experiments.

Funding for this research was provided by the National Science Foundation's Graduate Research Fellowship Program and the Applied Biodiversity Science NSF-IGERT Program at Texas A&M University (NSF-IGERT Award #0654377).

***SACHATAMIA CF. ALBOMACULATA* (Yellow-flecked Glass Frog). LIFE HISTORY.** S*achatamia albomaculata* is a glass frog from Central and South America. Savage (2002. The Reptiles and Amphibians of Costa Rica: A Herpetofauna between Two Continents, between Two Seas. Univ. Chicago Press, Chicago, Illinois. 934

FIG. 1. Amplectant pair of *Sachatamia cf. albomaculata*, Bilsa Biological Station, western Ecuador.

pp.) reports the species is commonly found calling from vegetation 1–2 m above rivers all year around. I found something quite different for this species during a 10-month field season at the Bilsa Biological Station in western Ecuador. I had four encounters with *S. albomaculata,* totalling eight individuals. During 87 h I spent surveying along rivers, *S. albomaculata* was only ever encountered as pairs in amplexus (Fig. 1). Juliet Burmingham (pers. comm.), who worked at Bilsa for close to a decade, also reports having only ever seen this species in amplexus and published a photograph of an amplectant pair (Ortega-Andrade et al. 2010. Check List 6[1]:119–154). Paul Hamilton (pers. comm.), who led a research expedition in La Perda, Ecuador (about 60 km SE of Bilsa), observed the same breeding behavior in 2009. This 100% encounter rate of individuals in amplexus suggests that this species spends most of its life in the canopy and only descends to breed, which is markedly different from Savage's (2002, *op. cit.*) description for the species in Central America. The populations in Ecuador are isolated by some 400 km from populations in northern Colombia and Central America. Furthermore, Guayasamin et al. (2006. Check List 2[1]:70–75) reports that *S. albomaculata* in Ecuador is morphologically different from populations in Central America, having larger dorsal spots. This morphological difference, the different breeding habits, and its geographic isolation from northern populations suggests that this could be a distinct species of *Sachatamia*. Molecular research and further morphological and acoustic studies are required to settle the assignment of this species as distinct or as an aberrant population.

***SCAPHIOPUS HOLBROOKI* (Eastern Spadefoot). POSSIBLE TRANSMITTER EXPULSION.** Expulsion of radio-transmitters via transintestinal absorption has been documented in fish (Meyer and Honebrink 2005. Trans. Amer. Fish. Soc. 134:602–606) and snakes (Pearson and Shine 2002. Herpetol. Rev. 33:261–263), and a study recently documented the first definitive account of radio-transmitter expulsion in amphibians (Tracy et al. 2011. Biol. Lett. 7:465–467), which reported the expulsion of transmitters in Cane Toads (*Rhinella marina*) via absorption through the bladder. As discussed in Tracy et al. (2011, *op. cit.*), with respect to anurans, this ability may be an adaptation to expelling objects (e.g., sticks or thorns) that may pierce their body cavity when landing during movement and/or to expel arthropod prey (or prey parts) that may burrow their way into the body cavity at some point during the digestive process.

During a radio-telemetry investigation of adult *Scaphiopus holbrooki* at Cape Cod National Seashore in Provincetown, Massachusetts (USA) during 2006, we observed three possible instances of radio-transmitter expulsion. In all three instances we found the radio-transmitters (model BD-2H, mass 1.7 g, Holohil Systems Ltd., Carp, Ontario, Canada; implanted into the body cavity) clean on the ground surface with no evidence of predation (i.e., no spadefoot remnants or predator fecal pellets found nearby, nor were there any scrapes on the radio-transmitter), and we found the transmitters on the ground surface 54 days (2 instances) and 111 days (1 instance) following radio-transmitter implantation surgeries. We observed two of these individuals alive on the surface during nocturnal telemetry surveys two nights prior to finding radio-transmitters on the surface. In addition, during radio-transmitter removal surgeries upon completion of fieldwork (132 days after radio-transmitter implantation), we noted that for 4 of the 8 individuals that underwent transmitter removal surgery the radio-transmitter was fully encapsulated in a thick, vascularized tissue, consistent with the finding by Tracy et al. (2011, *op. cit.*) for *Rhinella marina*, and were likely in the process of being voided from the body cavity. Unfortunately, we did not take note as to which internal organ this tissue was attached to, and thus cannot confirm if the route of expulsion is the same as that reported by Tracy et al. (2011, *op. cit.*; i.e., through the bladder).

Handling of animals was conducted under a University of Massachusetts Amherst Institutional Animal Care and Use Protocol and collection permits granted by the Massachusetts Division of Fisheries and Wildlife.

***SCINAX RUBER* (Red Snouted Treefrog). PREDATION.** Neotropical anurans are abundant, small to moderate sized, and are common prey for all classes of vertebrates and some arthropods. Various predaceous spiders feed on anurans (Menin et al. 2005. Phyllomedusa 4[1]:39–47; Toledo 2005. Herpetol. Rev. 36:395–400; Toledo et al. 2007. J. Zool. 271:170–177). In some cases the frogs are hunted, killed, and eaten by tarantulas and other hunting spiders. Few snakes have been reported as predators of *Scinax ruber* (Bernarde and Abe 2010. Biota Neotrop. 10[1]:167–173; Mendes-Pinto et al. 2011. Biofar 5[2]:122–126).

COLOR REPRODUCTION SUPPORTED BY THE THOMAS BEAUVAIS FUND

FIG. 1. A female Wandering Spider, *Phoneutria boliviensis*, preying on a Red-snouted Treefrog, *Scinax ruber*, near Chácara de Jesus, Rio Branco, Acre, Brazil.

On 11 June 2011, we found a recently killed *S. ruber* in Chácara de Jesus (9.911880°S, 67.767382°W, 173 m elev.), Rio Branco, Acre, Brazil. The frog was caught on a tree leaf by a female Wandering Spider, *Phoneutria boliviensis*, which had partially consumed the frog (Fig. 1). The posture of the frog led us to suspect that it was attacked from the side.

Photographs of the frog and the spider were deposited in the Coleção Herpetológica da Universidade Federal do Acre. We thank Dr. Adalberto J. Santos, Departamento de Zoologia, Instituto de Ciências Biológicas, Universidade Federal de Minas Gerais for the spider identification and Evan Twomey for valuable suggestions on this manuscript.

PAULO ROBERTO MELO-SAMPAIO (e-mail: prmelosampaio@gmail.com), **JÚNIOR MARCOS LIMA MACIEL, CAMILA MONTEIRO BRAGA DE OLIVEIRA, RAELLEN DA SILVA MOURA, LORENA CORINA BEZERRA DE LIMA,** União Educacional do Norte – Uninorte Alameda Hungria, 200, Jardim Europa II - CEP: 69.911-900 Rio Branco, AC – Brazil; **TALISSON RUY BATISTA DA SILVA,** Universidade Federal do Acre – Programa de Pós-Graduação em Ecologia e Manejo de Recursos Naturais CEP: 69.915-900 Rio Branco, AC – Brazil.

***TRACHYCEPHALUS TYPHONIUS*. PREY.** Predation among amphibians occurs when the predator-prey size relationship is favorable (Toledo et al. 2007. J. Zool. 271:170–177), and large frogs take larger prey including various vertebrates (Duellman and Trueb 1994. Biology of Amphibians. Johns Hopkins University Press, Baltimore, Maryland. 670 pp.). On 5 Aug 2011, at 2200 h in Porto Acre, Brazil (9.679851°S, 67.743126°W) an individual *Trachycephalus typhonius* (66 mm SVL) was found predating a *Dendropsophus leucophyllatus* (29 mm SVL) (Fig. 1) which was consumed head first. The specimens were captured and accessioned into the amphibian collection of the Universidade Federal do Acre (UFAC 5146, 5147). This is the first record of *D. leucophyllatus* as a prey item of *T. typhonius*.

TESTUDINES — TURTLES

***CARETTA CARETTA* (Loggerhead Seaturtle). DIET.** An adult female *Caretta caretta*, curved carapace length (CCL) of 91.5 cm, was found stranded on Arembepe Beach, northern part of Bahia, Brazil, on 19 September 2010 (12.75°S, 38.167°W). The turtle had a Porcupine Fish, *Cyclichthys spinosus* (Diodontidae), lodged in its buccal cavity (Fig. 1), and was bearing inconel tags on each front flipper (National Band Tag Co., USA), placed by Projeto TAMAR-ICMBio during 2004/2005 nesting season in Sergipe, nearly 260 km from the stranding site.

This is the first record of a Loggerhead Seaturtle ingesting a porcupine fish in Brazil. Loggerheads are primarily carnivorous and adults are generally bottom feeders. Despite eating opportunistic resources on the surface, they do not normally capture live fish (Dodd 1988. U.S. Fish Wild. Serv. Biol. Rep. 88[14]:1–110). In his extensive review of *C. caretta* prey taxa, Hughes (1974. S. Afr. Assoc. Mar. Biol. Res. Oceanogr. Res. Inst. Investigational Rep. 36:1–96) reported the ingestion of a porcupine fish in a South African study.

Limpus et al. (2008. Mar. Turt. Newsl. [120]:1–3.) found six cases of dead or moribund *C. caretta* with porcupine fish lodged in their mouths and throat. The authors suggested that the turtles might have fed on fish carcasses floating among discarded trawlers' bycatch. Fish can be intentionally ingested when found dead, or incidentally, when they capture medusa (Dodd 1988, *op. cit.*), and Loggerhead Seaturtles will presumably feed on fish bycatch discharged from fishing boats (Thomas et al. 2001. J. Zool. 255:525–532). The hypothesis of *C. caretta* feeding on dead fish was also supported by Bugoni et al. (2003. Chelon. Conserv. Biol. 4:685–688) by the co-occurrence of fish and the necrophagic isopod found in stomachs of stranded turtles.

The Porcupine Fish (*C. spinosus*) is commonly found in estuarine areas and occurs along the coast between Brazil and Argentina, in depths up to 190 m (Carvalho-Filho 1999. Peixes: Costa Brasileira. Editora Melro Ltda. São Paulo, SP. 3rd ed. 320 pp.), and has been reported as trawler bycatch (Bail and Branco 2003. Notas Técnicas. Facimar 7:73–82), suggesting that the turtle noted here had possibly ingested a dead or moribund fish.

***CARETTA CARETTA* (Loggerhead Seaturtle). EPIBIONT BIVALVES.** The neritic waters of the Baja California Peninsula (BCP) are one of the most important aggregation areas of juveniles of the North Pacific population of the Loggerhead Seaturtle. Though they nest exclusively at Japanese rookeries (Bowen et al. 1995. Proc. Natl. Acad. Sci. 92:3731–3734), some juveniles feed and grow to maturity in a relatively small area near the BCP, eventually returning to their Japanese breeding grounds (Nichols et al. 2000. Bull. Mar. Sci. 67:937–947; Peckham et al. 2011. Mar. Ecol. Prog. Ser. 425:269–280). The conservation status of this population, which was recently classified as Endangered (USFWS-NMFS 2011), requires special attention to elucidate their ecology and life history for proper species conservation. Loggerheads are the sea turtles most colonized by commensals, parasites, and symbiotic species (Frick et al. 2000. Mar. Turt. News. 88:3–5). Their carapace, plastron, and flippers represent habitat for several taxonomic groups, which has enabled the study of trophic relationships among epibiont community members (Frick et al. 2004. Southeast. Nat. 3[4]:613–620), the ecology of host turtles (Frazier et al.1992. Bull. Mar. Sci. 51:1–8), and the biogeographical patterns of sea turtle populations (Caine 1986. J. Exp. Mar. Biol. Ecol. 95:15–26).

The ecological constraints of epifaunistic habitats primarily consist of physical stabilization requirements and the ability for defense against predation (Frazier et al. 1985. Mar. Ecol. 6[2]:127–134). Loggerheads are typically found in tropical and temperate coastal waters (Dodd 1988. U.S. Fish Wildl. Serv. Biol. Rep. 88:100–110), coinciding with the ecology of their reported epibionts (Frick et al. 2002. Bull. Mar. Sci. 70[3]:953–956). The resting behavior of Loggerheads, in which they remain motionless at the sea floor, combined with the frequent peeling of their carapace result in facile attachment by mollusk larvae to the carapace (Frazier et al. 1985, *op. cit.*).

One hundred thirteen epibiont species have been documented to associate with Loggerheads nesting in North America, and on juveniles of the Spanish Mediterranean, ranging from Algae, Poriphera, Cnidaria, Mollusca, Platyhelminthes, Annelida, Arthropoda, and Urochordata (Badillo et al. 2001. *In* Margaritoulis and Demetropoulos [eds.], Proceedings of the First Mediterranean Conference on Marine Turtles, pp. 62–65; Caine 1986. J. Exp. Mar. Biol. Ecol. 95:12–26; Grammentz 1988. Naturalista Sicil. S. IV, XII [1–2]:33–46; Frick et al. 1998. Herpetol. Rev. 29[4]:211–214). Moreover, other detailed studies have been conducted on close relationships of several organisms with *C. caretta*, including *Balaenophilus* spp. (Ogawa et al. 1997. Zool. Sci. 14[4]:691–699), *Podocerus* spp. (Yamato 1992. Publ. Seto Mar. Biol. Lab. 35[4/5]:281–288), Cirripedia (Monroe and Limpus 1979. Mem. Queensland Mus. 19[3]:197–223; Stamper et al. 2005. J. Zoo Wildl. Med. 34[4]:635–641), and *Planes minutus* (Daveport 1994. J. Mar. Biol. Assoc. U.K. 74:735–737).

As part of the Grupo Tortuguero de las California's long term study of juvenile Loggerhead Seaturtles, in July 2011 we collected epibiont samples from the carapaces of 10 turtles (body mass 24.3–63.5 kg, and curved carapace length [CCL ± 0.1 cm] from 55–78.5 cm; mean CCL = 69.4 ± 6.9 cm) captured at Golfo de Ulloa (from El Vizcaino [27.8333°N, 115.0833°W] to Bahia Magdalena [24.5°N, 112.0°W]), Baja California Sur, Mexico. Typical of the region, all turtles carried barnacles (*Chelonibia testudinaria*), Amphipoda, red algae *Polysiphonia* sp., and some assorted bivalves. The microbivalve *Cymatioa pulchra* was present on one individual; the Winged Pearl Oyster (*Pteria sterna*; 0.1–0.4 g, and 11–13 mm length) and shell-loving oyster (*Ostrea conchaphila;* 27.7 g, and 53 mm length) were present in two and one turtles, respectively. The size of the oysters suggests that they were attached to the turtles for several months (Frick et al. 2002. Bull. Mar. Sci. 70[3]:953–956).

The ranges of the three epibiont species are within the limits of the tropical and subtropical habitats from California to Peru (Abbott 1974. American Seashells: The Marine Mollusca of the Atlantic and Pacific Coasts of North America, 2nd ed. Van Nostrand Reinhold Co., New York. 663 pp.). *C. pulchra* is generally symbiotic with other invertebrates to which it attaches with its byssus (Keen 1971. Seashells of Tropical West America. Stanford University Press, California. 854 pp.). The Winged Pearl Oyster, considered a potential resource for pearl production (i.e., mariculture) occupies epifaunal habitats continuously (Southgate 2008. *In* Southgate and Lucas [eds.], The Pearl Oyster, pp. 231–272. Elsevier, Oxford, UK); because of their planktonic larval phase substrate selection occurs prior to metamorphosis (Wada and Tëmkin 2008. *In* Southgate and Lucas, *op. cit.*, pp. 37–75). The shell-loving oyster is usually found attached to dead shells, rocks, and crab carapaces in depths up to 40 m (Abbott 1974, *op. cit.*).

High biological productivity of the Golfo de Ulloa and its sea surface temperature at neritic areas during the summer of 2011 (22.9 ± 1.3°C; from 19.1 to 24.6°C) allowed bivalves to have good metabolic rates. Research of growth and development of larvae and juveniles of these bivalve species suggests epibionts had been associated with the turtles at least 11 weeks, therefore Loggerheads were in neritic areas of the BCP several weeks before they were sampled for this study (Araya-Nunes et al. 1991. California Fish Game 77:181–193; del Rio-Portilla et al. 1992. Mar. Ecol. Prog. Ser. 89:221–227).

To our knowledge this is the first report of *C. pulchra*, *P. sterna,* and *O. conchaphila* associated with the carapaces of *C. caretta,* although symbioses have been reported between other molluscs and loggerheads (Caine 1986. J. Exp. Mar. Biol. Ecol. 95:1526). This represents a contribution to understanding of the ecology of both the bivalve and turtle species, with special emphasis on the interspecific relationships of immature turtles from the northern Pacific. We thank Alejandra Aguillón for her valuable help with taxonomic identifications.

***GOPHERUS AGASSIZII* (Mojave Desert Tortoise). DIET.** Research into the diet of the Mojave Desert Tortoise has documented occurrences of rock and soil consumption, infrequently observed instances of osteophagy, and only a single previous documentation of consumption of a tortoise carcass (Esque and Peters 1994. Fish and Wildlife Research 13:105–111; Walde et al. 2007. Southwest. Nat. 52[1]:147–149). Consumption of deteriorating bone matter is thought to provide calcium to the otherwise herbivorous tortoise diet, supplying a necessary nutrient that is not abundant in the tortoise's desert range.

On 27 May 2011, beginning at 1013 h, I observed a juvenile *Gopherus agassizii* (CL 170 mm) approximately 32 km W of Needles,

FIG. 1. Juvenile Mojave Desert Tortoise consuming skeletal remains of a dead conspecific.

California, USA (34.68°N, 115.04°W) consuming portions of the disarticulated skeleton of a conspecific (Fig. 1). I stood at a distance of 5–7 m observing for approximately 10 minutes, and took several photographs and videos. The tortoise repeatedly picked up, broke, and consumed portions of disarticulated plastron. Approximately 5 minutes after initial observation, the tortoise recognized my presence and paused the behavior, but resumed a minute or two later. Osteophagy of tortoise remains by Desert Tortoises may represent a more likely occurrence than the relative scarcity of observations suggest. The highly ossified skeletal structure and longevity of this species suggests Desert Tortoises may provide a net calcium sink in their desert ecosystems. Upon death, tortoise carcasses can provide a concentrated source of calcium available to many desert dwelling organisms.

***KINOSTERNON SUBRUBRUM* (Eastern Mud Turtle). DIET.** *Kinosternon subrubrum* is an omnivorous generalist, scavenging and preying on a wide variety of plants, vertebrates, and invertebrates (Ernst and Lovich 2009. Turtles of the United States and Canadá, 2nd ed. John Hopkins University Press, Baltimore, Maryland. 827 pp.). However, to our knowledge there are no reports of turtles consuming the shed skins of squamates. On 12 July 2012, we captured an adult female *K. subrubrum* on the Emory River across from the Tennessee Valley Authority Ash Recovery Site in Kingston, Tennessee, USA. Upon being held overnight, the turtle excreted portions of a shed snake skin. A large section of the skin protruded from the cloaca, confirming that it had been ingested. The pieces of the shed skin were relatively large and intact, suggesting limited digestion. Although precise identification of the snake was not possible, the keeled scales and size of the skin, together with our knowledge of the study site, strongly suggest *Nerodia sipedon*.

DAVID A. STEEN (e-mail: davidasteen@gmail.com), **KALEB Q. WEBB, HENRY J. VOGEL, TANIYAH D. PARKER, MICHELINA C. DZIADZIO,** and **WILLIAM A. HOPKINS,** Virginia Polytechnic Institute and State University, 106 Cheatham Hall, Blacksburg, Virginia 24061, USA.

***PODOCNEMIS ERYTHROCEPHALA* (Read-Headed Amazon River Turtle). KYPHOSIS.** Kyphosis is defined as "a dorsally convex deformity of the spine in the sagital plane of the animal" (Rhodin et. al. 1984. Brit. J. Herpetol. 6:369–373). Kyphosis is relatively widespread in many species of Cryptodira, however it has been reported for only one pleurodire, of the family Chelidae: *Emydura macquarii krefftii* (Limpus et. al. 2006. Marine and Freshwater Sciences Environmental Sciences Division. Conservation Technical and Data Report. 7:1–15; Trembath 2009. Chelon. Cons. Biol. 8:94–95). On 23 January 2008 we captured a kyphotic female *Podocnemis erythrocephala* (Fig. 1) in the Macacoapu branch of the Ayuanã River near its confluence with the Rio Negro, Amazonas, Brazil (0.5352694°S, 64.9253656°W; WGS 84). The turtle was an adult, 247 mm straight-line carapace length, 205 mm carapace width, and 202 mm plastron length. It weighed 1400 g and appeared to be in good health; it was marked and released at the site of capture. Trembath (*op. cit.*) commented that kyphosis is rare, even though it occurs in many different genera; he observed it in 0.36% of 833 individuals. In the Ayuanã River we marked 4432 *Podocnemis erythrocephala* (Bernhard and Vogt 2012. Herpetologica 68: *in press*) and found only one kyphotic turtle, 0.02% of the turtles collected. This is the first case reported for the Podocnemididae.

FIG. 1. Adult female *Podocnemis erythrocephala* with kyphosis.

The Project was financed by FAPEAM, Project Number 916/2003 Edital Temático. CNPq provided the scholarship for R. Bernhard in the postgraduate department of ecology of INPA. The Mayor's office of the Municipality of Santa Isabel do Rio Negro is thanked for logistical support. The study was authorized by IBAMA permit number 13346-1. We thank our field assistants, Ademir, Artur, Elis, Elizângela, Érica, Francesco, Guilherme, Joane, Larissa, Ramiro, Renato, Rodrigo, and Tania, for helping make this study possible.

***STERNOTHERUS CARINATUS* (Razor-backed Musk Turtle). REPRODUCTION.** On 25 June 2012 at ca. 1735 h I observed two *Sternotherus carinatus* copulating under natural conditions. The copulating turtles were behaving in a generalized kinosternid courtship pattern that has been previously described (Mahmoud 1967. Copeia 1967:314–319). Copulation was visibly confirmed both by the male mounting and clasping of the female from above and the biting behavior of the female. The turtles were observed at a water depth of 0.85 m near a large boulder in the upper Little River in Pushmahata Co., Oklahoma, USA (34.530333°N, 95.026667°W, 234 m elev.). The water temperature was 27.1°C. After the accidental disruption of the copulation, both turtles were captured, measured, and weighed. The male

had a plastron to carapace length (PL/CL) ratio of 0.70 (CL = 118.61 mm; PL = 83.55 mm) and weighed 280 g. The female had a PL/CL ratio of 0.72 (CL = 92.29 mm; PL = 66.02 mm) and weighed 180 g. This is apparently the first reported observation of *Sternotherus carinatus* mating in the wild.

***TERRAPENE ORNATA LUTEOLA* (Desert Box Turtle). DIET.** The ecology of *Terrapene ornata luteola* is poorly known, and in particular there is a notable paucity of information regarding diet (Ernst and Lovich 2009. Turtles of the United States and Canada. 2nd ed. Johns Hopkins University Press, Baltimore, Maryland. 827 pp.). We herein describe the diet of *T. o. luteola* collected in Presidio and Brewster counties, Texas, during 2008. To our knowledge, this is the first quantitative report on the diet of *T. o. luteola*. Our sample consisted of 14 turtles (mean carapace length = 121 mm; SD = 16 mm; range = 89–147 mm) opportunistically collected during June (1), July (5), August (3), and September (5); nine were found crossing highways, four encountered during the course of other field work, and one turtle was DOR. Turtles were found at elevations ranging from ca. 1065 to 1380 m in desert grassland with significant areas of shrub encroachment (Powell 1998. Trees and Shrubs of the Trans-Pecos and Adjacent Areas. University of Texas Press, Austin. 498 pp.). Precipitation in this region averages about 400 mm annually (Powell, *op. cit.*). We obtained feces by placing turtles overnight (12–18 h) in plastic buckets containing about 5 cm of water to stimulate defecation (Platt et al. 2009. Southeast. Nat. 8:335–346). The contents of each bucket were then passed over a sieve (2 mm mesh), and food items recovered, dried, and later identified to the lowest possible taxonomic level. We calculated the percent occurrence of each food item recovered as the number of samples in which a particular item occurred divided by the sample size. Percent occurrence is the appropriate metric when the number of individual food items cannot be quantified (Rosenberg and Cooper 1990. Stud. Avian Biol. 13:80–90). Each turtle was permanently marked by notching a unique series of marginal scutes (Cagle 1939. Copeia 1939:170–172) and released at the capture site within 48 h. We dissected the road-killed turtle, and removed, washed, sieved, dried, and later identified the gut contents.

Insect remains were recovered from every turtle (100%) in our sample. We identified the remains of dung beetles (Scarabaeidae), lady beetles (Coccinellidae), and grasshoppers (Caelifera) from 7 (50.0%), 2 (14.2%), and 1 (7.1%) turtles, respectively. The remains of insects we were unable to identify were recovered from 6 (42.8%) turtles. Similar to our results, others have found that insects comprise as much as 90% of the diet of *T. o. ornata*, with dung beetles being the most frequently consumed insect prey (Blair 1976. Southwest. Nat. 21:89–103; Legler 1960. Univ. Kansas Publ. Mus. Nat. Hist. 11:617–619; Metcalf and Metcalf 1970. Trans. Kansas Acad. Sci. 73:96–117). Representatives of seven Orders and 18 Families of insects have been reported in the diet of *T. ornata* (reviewed by Ernst and Lovich, *op. cit.*).

We recovered millipede (*Orthoporus* spp.) remains from 6 (42.8%) *T. o. luteola*, and observed a turtle consuming a living millipede (*Orthoporus ornatus*) on 30 August 2008. Millipedes (Diplopoda) have previously been reported in the diet of *T. ornata* (Ernst and Lovich, *op. cit.*). Millipedes secrete a variety of toxic compounds (e.g., hydrogen cyanide and benzoquinone) from glands in each body segment, which cause many predators to cease an attack and perform vigorous cleansing actions (Eisner and Meinwald 1966. Science 153:1341–1350). What effect, if any, these toxins have on *T. ornata* remains unknown; however, the prevalence of millipede remains found in our study and reported by others (Ernst and Lovich, *op. cit.*), strongly suggests these compounds do little to deter predation by *T. ornata*.

The molar of a small mammal found in the feces of one (7.1%) turtle perhaps originated from a carcass consumed as carrion. Scavenging of vertebrate carrion by *T. ornata* is well documented (Hill et al. 2005. Herpetol. Rev. 36:443; Jensen 1999. Herpetol. Rev. 30:95; Kolbe 1998. Herpetol. Rev. 29:235; Legler, *op. cit.*; Parker 1982. Southwest. Nat. 27:365). When available, carrion provides an energetically rich food that can be obtained safely without the cost of capturing and subduing prey (DeVault and Krochmal 2002. Herpetologica 58:429–436). Small stones were recovered from six (42.8%) turtles. The reasons underlying stone ingestion are unclear (Ernst and Lovich, *op. cit.*); stones could be ingested accidentally during feeding (Legler, *op. cit.*), although deliberate ingestion reportedly occurs among captives (Skorepa 1966. J. Ohio Herpetol. Soc. 5:108).

Unidentified leaves and seeds were each recovered from one (7.1%) turtle suggesting vegetation and fruit constitute a relatively minor component of the diet in our study area. However, our results could simply reflect the seasonal availability of foliage and fruit. Although considered "chiefly carnivorous," *T. ornata* is known to consume foliage and fruit from a wide variety of plants (Ernst and Lovich, *op. cit.*). Succulent vegetation is thought to serve as a significant source of water for *T. ornata* inhabiting arid regions (Nash and Gangloff 2010. Herpetol. Rev. 41:489; Thomasson 1980. Southwest. Nat. 25:438), and if available, large quantities of fruit may be consumed to the exclusion of other foods (Ernst et al. 1994. Turtles of the United States and Canada. Smithsonian Institution Press, Washington, D.C. 578 pp.). Some evidence suggests *T. o. ornata* might also play an important role in seed dispersal (Stone and Moll 2009. Southwest. Nat. 54:346–350).

We thank Andrew and Ali Berezin, Lourdes Crespo, and Lewis Medlock for assisting with turtle collection. Lewis Medlock supplied several important, but obscure, references. Support for this project was provided by a Research Enhancement Grant from Sul Ross State University to SGP. Turtles were collected under a scientific research permit issued by the Texas Department of Parks and Wildlife to SGP (SPR-0307-844). The findings and conclusions in this note are those of the authors and do not necessarily represent the views of the U.S. Fish and Wildlife Service.

SQUAMATA — LIZARDS

***ANOLIS CAROLINENSIS* (Green Anole). ATTEMPTED SAUROPHAGY.** Most species of *Anolis* lizards consume primarily insect prey (Andrews 1976. Copeia 1976:477–482; Schoener 1968.

FIG. 1. Adult male *Anolis carolinensis* (perched on residential air conditioning unit) attempting to consume a juvenile *Sceloporus undulatus hyacinthinus*.

Ecology 49:704–726). However, anoles are known to be relative dietary generalists, consuming what they opportunistically encounter and can capture and swallow, including spiders, centipedes, snails, seeds, and on occasion, small vertebrates (Losos 2009. Lizards in an Evolutionary Tree. Univ. California Press, Berkeley, California. 507 pp.). Reports on predation by anoles on other lizards are relatively rare, but anecdotal evidence of saurophagy in a number of *Anolis* species indicates that anole predation on small (often juvenile) lizards may be more frequent than generally thought, especially for adult male anoles (Gerber 1999. Anolis Newsletter V:28–39).

Anolis carolinensis is a well-studied species common throughout the southeastern United States. As with other anoles, this species is mainly insectivorous, but large males will occasionally prey on smaller conspecifics (e.g., Gerber and Echternacht 2000. Oecologia 124:599–607). Observations of saurophagy by *A. carolinensis* on non-anoline lizards remain rarely reported, but one previous account described an adult male *A. carolinensis* feeding on an adult *Sceloporus undulatus* carcass (Himes 1998. Herpetol. Rev. 29:236–237). Because both of these lizards had approximately the same snout–vent length (SVL), the author concluded that it was unlikely that the anole was capable of killing the *Sceloporus* lizard, suggesting that the anole encountered and began feeding on the *Sceloporus* after it had expired. Here, we describe a second account of *A. carolinensis* attempting to consume a *Sceloporus undulatus*.

On 19 October 2008, an adult male *A. carolinensis* was observed attempting to eat a juvenile *Sceloporus undulatus hyacinthinus* at the residence of the first author (TJH) in Wake Co, North Carolina, USA. A single digital photograph (Fig. 1) was taken during this process, which lasted approximately 10 minutes. The *A. carolinensis* repeatedly attempted to reposition and swallow the *Sceloporus*, with the anterior end of the lizard in its mouth, but eventually dropped and abandoned the dead *Sceloporus* when it was unable to do so. While no measurements were taken of these lizards, the *Sceloporus* appears to have at least 50% of the SVL of the green anole. Mahler and Glor (2011. Herpetol. Rev. 42:272–273) previously reported that an adult male *Anolis cybotes* was successfully able to swallow an *A. marron* individual that was 64.3% of its own SVL, but it appears that the failed predation attempt reported here resulted from the large size of the *Sceloporus*, preventing consumption by the *A. carolinensis*.

Box 167, Boerne, Texas 78006, USA (e-mail: gerardtsalmon@gmail.com); **MICHELE A. JOHNSON**, Department of Biology, Trinity University, San Antonio, Texas 78212, USA (email: mjohnso9@trinity.edu).

***ANOLIS SAGREI* (Brown Anole). PREY.** The anoles, family Polychrotidae, show an overwhelming dietary preference for invertebrates and Herrel et al. (2004. Oecologia 140:160–168) report that only 11.5% of species in this family are fruit eaters. Most frugivory reported in anoles has occurred among island-dwelling populations, and Herrel et al. (*op. cit.*) suggested that this may be due to low interspecific and high intraspecific competition on such islands. Most sources agree that *A. sagrei* does not prefer fruit (Herrel et al., *op. cit.*). This species has been observed to eat some "plant food" on Bimini, though details were not described (Schoener 1968. Ecology 49:704–726.).

In 2011, *Anolis sagrei* was observed eating fruit in two instances at the Palm Beach Zoo, Palm Beach Co., Florida, USA (26.667029°N, 80.069857°W). The first observation occurred on an unrecorded date in the month of March, where an adult male *A. sagrei* began consuming a fruit of a *Ficus* sp. on a paved footpath directly below a large *Ficus* sp. tree. The anole began eating the fruit shortly after it fell, perhaps indicating the consumption of the fruit was a result of a feeding response to movement. The second observation occurred 17 June at 1700 h and was photographically documented. In this instance, an adult female *A. sagrei* was observed running across a wooden railing with a *Ficus* sp. fruit in her mouth. In both instances there were other *A. sagrei* observed in the immediate area, the majority of them actively consuming ants.

Although fruit is not typically considered part of the diet of *A. sagrei*, no special adaptation is needed for insectivorous lizards to digest fruit pulp (Olesen and Valido 2003. Trends Ecol. Evol. 18:177–181). I have found one other instance of photographically or videographically documented fruit consumption by *A. sagrei*, an individual in the Bahamas was observed scavenging on the fruit of *Manilkara zapota* (AnoleAnnals.org/2010/12/05/frugivory-anolis-sagrei, accessed 18 May 2012).

JOSHUA D. HOLBROOK, Department of Biological Sciences, Florida Atlantic University, Davie, Florida 33314, USA; e-mail: JHolbro8@fau.edu.

***ANOLIS SAGREI* (Brown Anole). INTERSPECIFIC KLEPTOPARASITISM.** *Anolis sagrei* is a common, invasive anole in Florida and is usually found close to human habitation. In April 2012, an open-ended wooden box (25 cm x 15 cm) filled with lengths of hollow bamboo and dried stems of forbs to attract hole-nesting bees and wasps was placed on a pot of aloe plants (approx. 60 cm above the ground) in a suburban garden in central Florida. Two days later, a large male *A. sagrei* was observed displaying on top of it. A rival male perched within 60 cm of him. The estimated SVL for both males was approximately 50 mm. For the next two weeks both males were seen in the same place, one perched above the box, and one slightly below it, along with several females.

Two weeks after positioning the box, wasps and a carpenter bee were seen exploring it. The wasps appeared to be eumenine vespids, which are hole-nesting caterpillar hunters. Both male anoles ignored these hymenopterans. On another occasion a paper wasp (*Polistes* sp.) was seen chewing a projecting stem of bamboo, presumably to make carton for the construction of a nest. Again, this wasp was ignored by the two male anoles.

Two weeks and three days after positioning the box, one of the male anoles was observed to rapidly jump onto the box, appeared to shake something vigorously and then return to its perch above the box. When approached, it was seen to be eating a small yellow-green caterpillar. Approximately 15 min after this observation, a eumenine wasp was seen approaching the box carrying a caterpillar. Both male anoles were present by the box and both were seen to cock their heads as the wasp landed. The anole that had been seen eating the caterpillar previously immediately ran down from its perch (approx. 15 cm away), turned its head on one side and grabbed the caterpillar as soon as the wasp landed. The anole shook its head twice and then wiped the caterpillar roughly against the bamboo tubes. The wasp was dislodged at the first shake and immediately flew away. The anole returned to its perch and ate the caterpillar.

Over the next four days both anoles were seen to kleptoparasitize eumenine wasps attempting to land on the box. The male first observed kleptoparasitizing a wasp was seen stealing caterpillars twice more and the other male was seen to kleptoparasitize a wasp once. On all occasions the anoles were seen to turn their heads on their sides, pincer the caterpillar in their jaws and rapidly shake their heads once or twice. On one occasion a large carpenter bee approached and landed on the box, a male anole immediately ran at it presumably mistaking the bee for a wasp which it could kleptoparasitize, but turned away again and when the bee flew away the anole retreated so rapidly that it fell to the ground.

Kleptoparasitism has been observed in lizards such as Broadley's Flat Lizards (*Platysaurus broadleyi*) (Whiting and Greeff 1997. Copeia 1997:811–818) stealing figs from conspecifics, and Balearic Wall Lizards (*Podarcis lilfordi*) stealing pieces of pear from conspecifics (Cooper and Pérez-Mellado 2003. Amphibia-Reptilia 24:219–224), but I could find no previous record of kleptoparasitism between a lizard and an invertebrate. The territorial behavior of male anoles and the resource of the nesting tubes attracting eumenine wasps likely means that many more instances of kleptoparasitism occurred than were observed.

PHILIP W. BATEMAN, Archbold Biological Station, Lake Placid, P.O. Box 2057, Lake Placid, Florida 33862, USA; Department of Zoology and Entomology, University of Pretoria, Pretoria 0002, South Africa; e-mail: bill.bateman@zoology.up.ac.za.

***ANOLIS SAGREI* (Brown Anole). VOLUNTARY AUTOTOMY.** Caudal autotomy is a defense mechanism common to many lizard species whereby the tail is shed, usually to escape a predation event (Bateman and Fleming 2009. J. Zool. 277:1–14). Autotomy occurs along breakage planes in the tail vertebrae and is under central control of the lizard, i.e. it is not simply forced removal (Fleming et al. 2007. Biol. Rev. 82:481–510.). No studies, however, have convincingly demonstrated that autotomy in lizards can occur without the aid of at least some form of external resistance, although this has been recorded in some invertebrates (Fleming et al. *op. cit*).

We held several male and female wild-caught *Anolis sagrei* in captivity at Archbold Biological Station in May and June 2012. Each anole was kept singly in a 10 L clear plastic terrarium with a sand substrate, a water dish and a palm leaf stem for a perch. Several of these anoles demonstrated evidence of previous autotomy and regeneration of their tails. On 31 May 2012, a female anole (SVL 42 mm, tail length 53 mm) was observed to have autotomized her tail, which lay on the sand substrate directly beneath her favored perch. Forty-five mm of the tail had been autotomized (9 mm of the tip of the tail had been previously lost and regenerated), and 4 mm from the point of autotomy the tail was wounded on the dorsal surface, with a cut about 2 mm in length, that had bled recently. This wound had been noted at the time of capture 18 days before and had failed to heal in that time, perhaps because it was at a flex point.

Apart from having food and water added to the terrarium every second day the anole was never handled or disturbed. The tail appeared to have been shed without being caught or trapped and therefore without any external resistance; it seems likely that the female voluntarily shed the tail in response to the unhealed wound and that this is therefore comparable to autotomy behavior observed in some invertebrates.

Although there has been anecdotal discussion of lizards that autotomize tails when in collection bags and not otherwise restrained, we could find no similar observations of caudal autotomy in response to a wound and with no apparent external resistance. This adds to the adaptive benefits of caudal autotomy in lizards: not only does it allow a lizard to escape from predators (see Bateman and Fleming, *op. cit.* for a review) but it also allows a lizard to deal with a wounded, but unautotomized, tail.

BATEMAN**, Archbold Biological Station, Lake Placid, PO Box 2057, Lake Placid, Florida 33862, USA; Department of Zoology and Entomology, University of Pretoria, Pretoria 0002, South Africa (e-mail: bill.bateman@zoology.up.ac.za).

***ANOLIS UTILENSIS* (Utila Anole). HABITAT.** *Anolis utilensis*, a member of the *pentaprion*-group, is endemic to Isla de Utila (Islas de la Bahia), located off the north coast of Honduras. This anole has thus far only been described from two areas of mangrove swamp forest on Utila (Gutsche et al. 2004. Salamandra 40:297–302; Köhler 2008. Reptiles of Central America. Herpeton, Offenbach. 400 pp.; Kramer 2010. Iguana-Rundschreiben 23:5–9). It is arboreal and well-camouflaged due to a lichenose gray-brown dorsal pattern and exhibits gecko-like behaviors. Based on limited locality information, *A. utilensis* was regarded as being exclusive to mangrove forest habitat. Here, we report on a novel habitat type for this species.

On 21 April 2011, we detected a male specimen of *A. utilensis* about 300 m S of the so-called "Bat Cave" near Pumpkin Hill, a volcano remnant in the north east of Utila. The anole was sitting on a fence post at a height of ca. 1.5 m directly at the edge of a dirt road. This locality (16.118739°N, 86.886136°W, WGS84; 8 m elev.) was about 850 m away in linear distance from each of the two areas where *A. utilensis* is also known to occur. The closest mangrove forest is ca. 250 m NW from this new location. The surrounding area of the new locality consisted of broadleaf forest with various bushes, and farmland. The ground was dry soil and loosely covered with leaves; the location was partly shaded by tree canopy.

The habitat type for this new locality is completely different from that reported previously. Mangrove forest is characterized by high humidity, lower average temperature, and the presence

of salt and/or brackish water (e.g., Gutsche et al. 2004, *op. cit.*), while the new locality was predominantly dry and only influenced by rain water. Andrea Martinez (IRBS) reported several observations of *A. utilensis* within the vicinity where we found the specimen reported here (A. Martinez, pers. comm. 2011). The occurrence of *A. utilensis* here suggests that this species is not restricted to mangrove forest and likely occurs in other locations on Isla de Utila. However, we recognize that our observation may reflect a displacement effect due to on-going deforestation in mangrove habitat, as also has been suggested for the endemic mangrove iguana *Ctenosaura bakeri* (Pasachnik et al. 2009. Conserv. Gen. 10:1247–1254).

The anole was caught and brought to the local Iguana-Station (IRBS) for identification. We also took digital photographs of the animal including its diagnostic characters, and subsequently released the lizard at the site of capture. The photographs were sent to G. Köhler, the describer of *A. utilensis*, who verified our initial identification.

We thank G. Köhler for verifying the identification of *A. utilensis*, and A. Gutsche for providing literature and helpful comments to the manuscript.

MARTIN HALLMEN, Wilhelmstraße 11a, 63526 Erlensee, Germany (e-mail: Hallmen@t-online.de); **ANDREAS HUY**, Dr.-Schultheiss-Straße 52, 66386 Sankt Ingbert, Germany (e-mail: andreashuy@online.de).

***ASPIODOSCELIS LABIALIS* (Baja California Whiptail). REPRODUCTION.** *Aspidoscelis labialis* is known from a narrow distribution along the Pacific coast from just south of Ensenada, Baja California, Mexico to 6 km SE of Guerrero Negro, Baja California Sur, Mexico (Grismer 2002. Amphibians and Reptiles of Baja California Including its Pacific Islands and the Islands in the Sea of Cortés. University of California Press, Berkeley. 399 pp.). A sample of 7 males (mean SVL = 51.3 mm ± 2.6 SD, range = 48–55 mm) and 13 females (mean SVL = 52.6 mm ± 4.2.SD, range = 48–58 mm) was examined from Baja California, Mexico collected in 1964, 1967, 1968, 1971, 1982. The specimens examined were those deposited in the herpetology collections of the Natural History Museum of Los Angeles County (LACM), Los Angeles, California, USA (as LACM: 67354, 75404–75411, 75418, 75620, 75622, 75624, 78803, 78804, 109658, 114809, 134679, 135468) and the Museum of Vertebrate Zoology (MVZ), University of California, Berkeley, California, USA (as MVZ: 78803, 78804).

A small slit was made in the left side of the abdomen and the left testis was removed from males and the left ovary was removed from females for histological examination. Enlarged ovarian follicles (> 5 mm) or oviductal eggs were counted in situ. No histology was performed on them. Removed gonads were embedded in paraffin, sections were cut at 5 µm and stained by Harris' hematoxylin followed by eosin counterstain. Histology slides are deposited in LACM and MVZ.

Two stages were noted in the testicular cycle: 1) spermiogenesis (seminiferous tubules lined by clusters of sperm and/or metamorphosing spermatids); 2) regressed = post breeding (seminiferous tubules contain spermatogonia and Sertoli cells). Monthly distribution of stages in the testicular cycle were: April (N = 1) spermiogenesis; May (N = 1) spermiogenesis; June (N = 4) spermiogenesis; August (N = 1) regressed. The smallest reproductively active male (undergoing spermiogenesis) measured 48 mm SVL (LACM 75407) and was collected in June.

Four stages were present in the ovarian cycle of *A. labialis* (Table 1): 1) Quiescent, no yolk deposition; 2) Early yolk deposition, vitellogenic granules in ooplasm; 3) Enlarged follicles (> 5 mm); 4) Oviductal eggs. Three March females had not yet commenced reproductive activity. Females from May and June contained oviductal eggs. One June female exhibited early yolk deposition indicating reproduction would likely continue into July. Whether a second clutch is produced in the same season is not known. Mean clutch size for seven females was 1.71 ± 0.95 SD, range = 1–3. The smallest reproductively active female (oviductal egg) measured 48 mm SVL (LACM 75406) and was collected in June. My findings confirm *A. labialis* has a spring to summer breeding season as suggested by Grismer (*op. cit.*).

Table 1. Monthly stages in the ovarian cycle of *Aspidoscelis labialis*.

Month	N	Quiescent	Early yolk deposition	Enlarged follicles	Oviductal eggs
March	3	3	0	0	0
May	1	0	0	0	1
June	9	2	1	3	3

I thank C. Thacker (LACM) and C. Spencer (MVZ) for permission to examine *A. labialis*.

STEPHEN R. GOLDBERG, Department of Biology, Whittier College, Whittier, California 90608, USA (e-mail: sgoldberg@whittier.edu).

***ASPIDOSCELIS LABIALIS* (Baja California Whiptail). ENDOPARASITES.** *Aspidoscelis labialis* is known from a narrow distribution along the Pacific coast from just south of Ensenada, Baja California, Mexico to 6 km SE of Guerrero Negro, Baja California Sur, Mexico (Grismer 2002. Amphibians and Reptiles of Baja California Including its Pacific Islands and the Islands in the Sea of Cortés. University of California Press, Berkeley. 399 pp.). We know of no reports of helminths from *A. labialis*. The purpose of this note is to establish the initial helminth list for *A. labialis*.

Five *A. labialis* (mean SVL = 51.8 mm ± 2.9 SD, range = 49–55 mm) deposited in the herpetology collection of the Natural History Museum of Los Angeles County (LACM), Los Angeles, California, USA as LACM 67354, collected May 1967 at Camalú, Baja California, Mexico (30.8396°N, 116.0614°W, WGS84, elev. 21 m) and LACM 75405, 75414, 75619, 75621 collected June 1971 at Colnett, Baja California, Mexico (31.0667°N, 116.2000°W, WGS84, elev. 55 m) were examined for helminths.

The body cavity was opened and the digestive tract removed, opened by a longitudinal incision and examined under a dissecting microscope. Cestodes (from the small intestines) were regressively stained in hematoxylin, mounted in Canada balsam, studied using a compound microscope and identified as *Oochoristica bivitellobata* (prevalence: number infected/number examined × 100 = 40%, mean intensity: mean number infected individuals ± 1 SD = 2.5 ± 2.1 SD, range = 1–4). Nematodes (from the small and large intestines) were cleared in a drop of lactophenol on a glass slide, coverslipped, studied using a compound microscope and identified as *Pharyngodon warneri*, (prevalence = 60%, mean intensity = 7.0 ± 3.5 SD, range = 5–11). Helminths were deposited in the United States National Parasite Collection, Beltsville, Maryland, USA as *Oochoristica bivitellobata* (USNPC 105792) and *Pharyngodon warneri* (USNPC 105793).

Oochoristica bivitellobata and *P. warneri* are, to date, known only from teiid lizards. A host list for *O. bivitellobata* can be found in Bursey and Goldberg (2011. Comp. Parasitol. 78:312–315) and a host list for *P. warneri* in Goldberg et al. (1997. Great Basin Nat. 57:273–277). *Aspidoscelis hyperythra* (Goldberg and Bursey

2003. Herpetol. Rev. 34:142) should be added to the host list for *P. warneri*. *Aspidoscelis labialis* is the seventeenth teiid species reported to harbor *O. bivitellobata* and the tenth to harbor *P. warneri*. *Aspidoscelis labialis* represents a new host record and Baja California, Mexico is a new locality record for both *Oochoristica bivitellobata* and *Pharyngodon warneri*.

We thank C. Thacker (LACM) for permission to examine *A. labialis*.

***ASPIDOSCELIS SEXLINEATA* (Six-lined Racerunner). COMMENSALISM.** *Aspidoscelis sexlineata* is a common teiid in Arkansas and Louisiana where it occupies open areas and requires exposed soil to hibernate and retreat from extreme temperatures (Dundee and Rossman 1989. The Amphibians and Reptiles of Louisiana. Louisiana State Univ. Press, Baton Rouge. 300 pp.; Trauth et al. 2004. The Amphibians and Reptiles of Arkansas. Univ. Arkansas Press, Fayetteville. 421 pp.). *Aspidoscelis sexlineata* may benefit from using the microhabitat of burrows of other vertebrates, specifically for thermoregulation. This species has been recorded as a burrow commensal of Gopher Tortoise (*Gopherus polyphemus*; Lips 1991. J. Herpetol. 25:477–481; Witz et al. 1991. Am. Midl. Nat. 126:152–158), Oldfield Deermouse (*Peromyscus polionotus*; Pearson and Nelson 1952. Copeia 1952:188–189), and Black-tailed Prairie Dog (*Cynomys ludovicianus*; Kretzer and Cully 2001. Southwest. Nat. 46:171–177). Pocket gophers (*Geomys* spp., *Thomomys* spp.) are a common group of fossorial rodents known for soil alteration via burrowing. This microhabitat created by pocket gophers provides habitat for a variety of organisms, including lizards. *Aspidoscelis sexlineata* were commonly encountered occupying the same habitat of Ozark Pocket Gophers (*Geomys bursarius ozarkensis*) in Arkansas but were never directly captured in a burrow (Connior et al. 2008. J. Arkansas Acad. Sci. 62:45–51). This teiid has been documented using the abandoned burrows of pocket gophers as retreats in Colorado (Vaughan 1961. J. Mammal. 42:171–174) and has been found in the mounds of Southeastern Pocket Gopher (*Geomys pinetis*) in Florida (Funderburg and Lee 1968. J. Herpetol. 1:99–100). Herein, we provide additional evidence to support commensalism between *A. sexlineata* and pocket gophers.

On 14 April 2008, while excavating a Baird's Pocket Gopher (*Geomys breviceps*) near Heber Springs, Cleburne Co., Arkansas, USA (35.448200°N, 92.084685°W; no datum available), an adult *A. sexlineata* was captured by SWC as it ran out of a freshly exposed pocket gopher tunnel. The individual was hand captured and identified to species. On 25 October 2009, while excavating a Baird's Pocket Gopher mound near Junction City, Claiborne Parish, Louisiana, USA (32.999252°N, 92.750636°W) a juvenile *A. sexlineata* was discovered in the mound by MBC. This specimen was deposited as a voucher specimen in the Arkansas State Museum of Zoology Herpetology Collection (ASUMZ 31388). Both of these areas were dominated by a variety of low-growing grasses and forbs without any other shade providing vegetation within the vicinity (~50 m). Ectotherms, specifically *A. sexlineata*, have minimal microhabitat to utilize for retreat from extreme ambient temperatures within this habitat. Historically, these areas were dominated by woody vegetation but the habitat has been altered to a landscape comprised of low-growing grasses and forbs. Historically, *A. sexlineata* probably did not primarily rely on the pocket gopher burrows for thermoregulation due to other available habitat characteristics (e.g., woody canopy cover). However, *A. sexlineata* has developed an apparent commensal relationship with pocket gophers due to current habitat characteristics resulting from alteration and the lizard possibly has not had a long term temporally dependent commensal relationship with pocket gophers within these altered areas. However, if the habitat remains altered in its current state, long term temporal commensalism between *A. sexlineata* and pocket gophers may persist.

These observations are the first documented records of *A. sexlineata* utilizing Baird's Pocket Gopher burrow systems as habitat. Although active pocket gopher burrows are typically closed off to the surface except for short durations of burrow maintenance, this microhabitat does provide important habitat for ectotherms. For instance, the sun-exposed dirt mounds provide areas for thermoregulation during cool ambient temperatures and abandoned pocket gopher burrows and mounds also allow refugia to retreat from warm ambient temperatures, especially in habitat that is dominated by low-lying vegetation and minimal shade providing cover. In a simulated burrow system containing both pocket gopher and *A. sexlineata*, the gophers only occasionally paused when the lizards ran by in the burrow (Hickman 1977. Texas J. Sci. 29:235–243), suggesting no negative physical or physiological interactions between the lizards and gophers. By providing thermoregulation sites and refugia for *A. sexlineata* and not any predation pressure, pocket gopher burrow systems may be an important habitat component for these lizards where they coexist. Furthermore, our observations when combined with other literature accounts lend evidence to a commensal relationship between *A. sexlineata* and other burrowing vertebrates.

MATTHEW B. CONNIOR, Health and Natural Sciences, South Arkansas Community College, El Dorado, Arkansas 71730, USA (e-mail: mconnior@southark.edu); **STEPHEN W. CHORDAS III,** Center for Life Sciences Education, The Ohio State University, 1735 Neil Avenue, Columbus, Ohio 43210, USA.

***CALLOPISTES MACULATUS* (Chilean Racerunner). PREY.** The diet of *Callopistes maculatus* is well documented from southern populations (Donoso-Barros 1961. Rev. Chil. Hist. Nat. 55:41–54; Donoso-Barros 1966. Reptiles de Chile. Ediciones de la Universidad de Chile. 458 pp.; Fuentes 1976. Ecology 57:3–17; Simonetti and Yañez 1984. Herpetol. Rev. 15:17), but few data are reported for northern populations. This species exhibits substantial plasticity in its food habits; its diet appears to depend on local and temporal prey availability (Castro et al. 1991. J. Herpetol. 25:127–129). Prey items that have been reported for this species include insects, seeds, lizards (*Liolaemus*), small snakes (*Tachymenis*), and rodents (*Abrothrix olivaceus* and *Octodon degus*).

For northern populations at Fray Jorge National Park (30.634167°S, 71.6675°W), Mellado (1982. Doñana Acta Vertebrata 9:372) reported preferences for micromammals (*Abrothrix olivaceus*, 74.3%) and secondarily, arthropods (21.2%) and *Liolaemus* lizards (4.5%). However, populations at Las Chinchillas National Reserve demonstrated a preference for insects (83.8%), and secondarily for mammals (8.9%) and reptiles (3.5%) with a record of predation on *Philodryas chamissonis*. Vidal and Ortiz (2003. Herpetol. Rev. 34:364–365) reported cannibalism, with a male hunting a juvenile female in the locality of Chacrita, Vallenar, Atacama region (28.39425°S, 70.713722°W, elev. 644 m).

At 1120 h on 18 October 2010, during a biodiversity study of Quebrada El Leon, Caldera, Atacama Province, Chile (26.958722°S, 70.737194°W; elev. 270 m) I observed an adult *C. m. atacamensis* capture a juvenile Darwin's Leaf-eared Mouse (*Phyllotis darwini*) behind a 1 m diameter rock surrounded by shrubs. The teiid then took the rodent to a small cave where it was consumed.

The lizard was an adult female (SVL = 166.5 mm; tail length = 230.4 mm) and was deposited in the Colección de Vertebrados de Zonas Áridas (CVZA 0148) of the Centro Regional de Investigación y Desarrollo Sustentable de Atacama (CRIDESAT) at the Atacama University. This is the northernmost observation concerning the diet of this species, and *Phyllotis darwini* is a new prey species reported for the diet of this teiid. I thank Carolina Urra for field assistance and Robert Langstroth and Cristián Abdala for revision of manuscript.

PABLO VALLADARES FAÚNDEZ, Departamento de Biología, Facultad de Ciencias, Universidad de Tarapacá, Velásquez 1775, Arica, Chile; e-mail: pvalladares@uta.cl.

***CALOTES VERSICOLOR* (Common Garden Lizard). AVIAN PREDATION.** *Calotes versicolor* is widely distributed in various habitats of the Indian subcontinent (Sharma 2002. The Fauna of India and the Adjacent Countries-Reptilia [Sauria] Vol. II. Director, Zoological Survey of India, Kolkata. 430 pp.). This species is known to be an ambush predator and also is known for its versatile camouflage abilities (i.e. to change color according to the surroundings). Several aspects of its ecology are well known, however, very little is known about its natural avian predators. The common known predators of *C. versicolor* are various snakes and large-sized lizards. Recently we observed this lizard being predated by a bird, the Shikra (*Accipiter badius*). This bird normally preys on small lizards such as skinks. Here we report a new known predator of *C. versicolor*.

PHOTO BY VIVEK SHARMA

FIG. 1. Shikra (*Accipiter badius*) predating an adult *Calotes versicolor*.

On 17 July 2010 at 1545 h, during a survey in Jiwaji University campus, Gwalior, Madhya Pradesh, India (26.5393°N, 77.75685°E; 119 m elev.), we observed an adult Shikra predating an adult male *C. versicolor* approx. 15 cm SVL (Fig. 1). The habitat where this observation occurred was comprised of dense canopy cover dominated by *Azadirachta indica, Mangifera indica,* and *Prosopis juliflora*. During our observation, a flying Shikra suddenly came down on the ground and grabbed the lizard in its talons and took it to a tree (*Prosopis juliflora*). This observation is the first photographic evidence of the predation of *Accipiter badius* on an adult *Calotes versicolor*.

This research was supported by the financial assistance from the Department of Science and Technology, New Delhi, India.

***HELODERMA HORRIDUM CHARLESBOGERTI* (Guatemalan Beaded Lizard). SHELTER USE.** *Heloderma horridum charlesbogerti* is endemic to the dry forests of Motagua Valley in eastern Guatemala and considered endangered. This subspecies is the only allopatric population of *H. horridum* and differs from other subspecies in coloration and attains a smaller size (Campbell and Vannini 1988. J. Herpetol. 22:457–468). Lizards of the genus *Heloderma* are considered nest specialist predators (Beck 2005. Biology of Gila monsters and Beaded Lizards. Univ. California Press, Los Angeles. 211 pp.).

We conducted a five-year radio-tracking study from July 2004 to September 2008 to investigate the ecology and behavior of *Heloderma horridum charlesbogerti*. Lizards were fitted with a radio transmitter (CHP-5P by Telonics, Mesa, Arizona, USA) and tracked using an ATS FieldMaster FM100 Receptor. The transmitters were attached within the second and third tail ring of each lizard (approx. 20 mm posterior to the vent). To improve the security of the transmitters, they were fixed using duct tape (Truper, USA), with care taken not to obstruct the cloaca. Each individual was also marked with PIT-tags (AVID microchips, Los Angeles, California, USA) inserted at the level of the right forelimb. The lizards were tracked using the homing method (White and Garrot 1990. Analysis of Wildlife Radio-tracking Data. Academic Press, San Diego. California. 383 pp.).

On 16 May 2007, we observed a female *H. h. charlesbogerti* hidden inside an underground nest of a bird of the family Momotidae, presumably of the species *Momotus mexicanus* (Russet-crowned Motmot) (Fig. 1). We did not observe any sign of bird activity within this nest or other surrounding nests that were ca. 50 cm away. This observation was made outside the breeding season of this bird, suggesting that this lizard was actively using the shelters as refugia and not predating the nest.

Another striking observation we made is that these lizards use temporal bodies of water that form within cavities of tree trunks at the beginning of the rainy season. We have observed this behavior in four different individuals on five different occasions. All of these observations were made at the beginning of the rainy season in July and August. On 29 July 2006, at 1030 h, a female

FIG. 1. Female *Heloderma horridum charlesbogerti* taken out from a momotid nest that it was using as shelter.

FIG. 2. Male *Heloderma horridum charlesbogerti* submerged into a body of water located in a cavity at the base of a Jocote Tree (*Spondias purpurea*).

H. h. charlesbogerti (No. 094.519.273; 295.mm SVL) was encountered in a flooded tree cavity at the beginning of the rainy season. This cavity was 2.58 m above the ground, located between two branches of the tree *Albizia idiopoda*. On 22 August 2006, a male (No. 094.333.040; 335 mm SVL) was found completely submerged in a body of water located in a cavity at the base of a Jocote Tree (*Spondias purpurea*), at a height of 0.20 m above the ground. It remained submerged for 18 min before lifting its head above the surface of the water (Fig. 2). All the other lizards were found resting with a portion of their heads held out of the water. On 17 August 2007, subadult No. 094.266.624 was encountered within a temporal water body within a cavity in the trunk of a *Leucaena diversifolia* tree, located 1.69 m above the ground. The cavities where the juvenile (No. 094.513.073) was found on two separate occasions were located in the trunk of a *Haematoxylon brasilleto* tree at 1.18 m above the ground (1 August 2007) and in a *Leucaena diversifolia* trunk at 1.32 m above the ground (21 July 2008). The average depth of water in these cavities was 39 ± 6 cm (N = 5).

The two new types of shelters used by helodermatid lizards presented in this report provide important implications in helping to understand the behavior and ecology of this species. The use of nest cavities dug out by birds of the Momotidae, such as *Momotus mexicanus,* as well as *Eumomota superciliosa,* could be for feeding purposes. The cavities are used by these birds during the beginning of the rainy season for laying eggs (Howell and Webb 2000. A Guide to the Birds of Mexico and Northern Central America. Oxford Univ. Press, Oxford. 851 pp.). It is possible that *H. h. charlesbogerti* uses these cavities because they are of difficult access to potential predators of this lizard, being located on steep cliffs, while also providing a relevant food resource.

The use of flooded tree cavities as shelters at the beginning of the rainy season may help explain a well-known behavior of captive helodermatid lizards. In captivity these lizards usually spend considerable time submerged in their water dishes, sometimes for more than 30 minutes or even a whole day (Beck 2005, *op. cit.*). It was previously believed that helodermatid lizards in the wild do not require the existence of above-ground water sources, but the water bodies used by the lizards tracked during this study had water from mid-June to late October (i.e., the rainy season). We suggest that this behavior observed in captivity is a reflection of the behavior in nature, where this species remains submerged in water at the beginning of the rainy season. This behavior probably evolved as a means to recover from severe dehydration suffered during aestivation in the dry season.

Fieldwork was conducted under CONAP permits. Funding was provided by grants from Zoo Atlanta, IRCF, Eli Lilly Co., Disney Worldwide Conservation Fund, San Diego Zoo, Oklahoma City Zoo, and The Nature Conservancy. This work was part of the Master's thesis of D. Ariano-Sánchez. Field assistance was provided by Erick Lopez, Cristian Beza, and Pablo Salazar.

DANIEL ARIANO-SÁNCHEZ (e-mail: darianosanchez@gmail.com) and **GILBERTO SALAZAR**, Asociación Zootropic, 12 calle 1-25 zona 1, Guatemala City, Guatemala.

***HEMIDACTYLUS MABOUIA* (Wood Slave). PREDATION.** The African gekkonid lizard *Hemidactylus mabouia* is an exotic species in Brazil and is frequently associated with human dwellings (Ávila-Pires 1995. Lizards of Brazilian Amazonia (Reptilia: Squamata). Zoologische Verhandelingen, Leiden. 706 pp.; Vanzolini 1978. Pap. Avul. Zool. 31:307–343). Lizards can fall prey to many arthropods, including insects, spiders, centipedes and amblypygids (Zug et al. 2001. Herpetology: An Introductory Biology of Amphibians and Reptiles. 2nd ed. Academic Press, San Diego, California. 630 pp.) with several cases described in the literature (see Bauer 1990. Herpetol. Rev. 21:83–87).

The scorpion *Tityus metuendus* lives in tropical forests of Western Amazon in Brazil and Peru. It occurs in the Brazilian states of Amazonas, Pará, Acre, Rondônia, and Roraima

(Lourenço 2002. *In* Adis [ed.], Amazonian Arachnida and Myriapoda, pp. 399–438. Pensoft Publishers, Moscow). Scorpions are mainly insectivorous, but small vertebrates can be part of their diet (Cândido 1999. *In* Joly and Bicudo [eds.], Biodiversidade do Estado de São Paulo, pp. 25–34. Fundação de Amparo à Pesquisa do Estado de São Paulo, São Paulo). A predation event on *Hemidactylus mabouya* by *Tityus metuendus* is reported here.

On 16 December 2009 in a residence located in the suburbs of the municipality of Porto Velho, state of Rondônia, northern Brazil (08.7619°S, 63.9038° W) surrounded by forest, a female *H. mabouia* (SVL = 0.8 mm) was observed at ca. 2200 h being attacked by a female *T. metuendus* (SVL = 60.7 mm) on an external wooden wall at the back of the residence, at approximately 110 cm above the ground.

At the moment of observation, the lizard was still struggling, dying minutes later from the scorpion's venom. There were other specimens of *H. mabouia* nearby, foraging under the residence's light. The two specimens observed in the predator-prey interaction were collected and deposited as vouchers in the herpetological collection of Universidade Federal do Acre (*H. mabouia*, UFACF 2471) and invertebrate collection of Instituto de Pesquisas da Amazônia, INPA (*T. metuendus*, INPA 0723).

SAYMON DE ALBUQUERQUE, Programa de Pós-Graduação em Ecologia e Manejo de Recursos Naturais, Universidade Federal do Acre, 69915-900, Rio Branco, Acre State, Brazil; e-mail: albuquerque-saymon@gmail.com.

***HEMIDACTYLUS MABOUIA* (Wood Slave). PREDATION.** *Hemidactylus mabouia* is native to Africa, widely distributed in the Americas (Vanzolini 1978. Pap. Avul. Zool. 3:307–343). It is found in different ecosystems in Brazil, mainly inhabiting urbanized areas (Rocha and Anjos 2007. Braz. J. Biol. 67:485–491; Rocha et al. 2011. Zoologia 28:747–754). *H. mabouia* appears to be an important prey item for some *Tropidurus* species, having been reported in the diet of *T. torquatus* in dune areas of the Brazilian coast (Araújo 1991. Rev. Brasil. Biol. 51:857–65). *Tropidurus hispidus* is a relatively large lizard reaching 35 cm total length (Freitas and Silva 2005. *In* Guia Ilustrado. A Herpetofauna da Mata Atlântica Nordestina. 161 pp.), and is a habitat generalist, often occuring near human dwellings (Rodrigues 1987. Arq. Zool. 31:105–230). The diet of *T. hispidus* consists mainly of insects, millipedes, gastropods, plant matter, and small vertebrates (Riberiro and Freire 2011. Iheringia, Sér. Zool. 101:225–232; Vanzolini et al. 1980. *In* Répteis das Caatingas. 161 pp.; Vitt 1995. Occas. Papers. Oklahoma Mus.Nat. Hist. 1:1–29).

PHOTO BY LEONARDO BARBOSA DA SILVA

FIG. 1. Predation of *Hemidactylus mabouia* by *Tropidurus hispidus* in the Parque Estadual Dois Irmãos, Recife city, Pernambuco, Brazil.

On 22 April 2011 at 1320 h, we observed a *T. hispidus* chasing a *H. mabouia* on a tree trunk. The decomposing trunk was a height of about 1.50 m from the ground on the edge of a forested area located in the Parque Estadual de Dois Irmãos, Recife City, Pernambuco, Brazil (8.001°S, 30.950°W; WGS 84). The gecko was captured by the *Tropidurus* by the hind limbs, followed by the *Tropidurus* grasping the gecko near the head and ingesting it. The predation event took about 5 minutes. This is the first record of predation reported for the species *H. mabouia* by *T. hispidus* in the northeast region of Brazil. The images of predation were filed in the collection of images of Herpetological and Paleoherpetological laboratory of Federal Rural University of Pernambuco - UFRPE, Recife, Pernambuco, Brazil.

We acknowledge the direction of Parque Estadual de Dois Irmãos for permission to carry out the research.

LEONARDO BARBOSA DA SILVA (e-mail: lb_silva@yahoo.com.br), **JACILENE BEZERRA DA SILVA, SÉRGIO LUIZ DA SILVA MUNIZ, EDNILZA MARANHÃO DOS SANTOS** and **GERALDO JORGE BARBOSA DE MOURA**, Universidade Federal Rural de Pernambuco, UFRPE, Paleoherpetological and Herpetological Laboratory, Rua Dom Manoel de Medeiros, s/n, Dois Irmãos, CEP: 52171-900, Recife, Pernambuco, Brazil.

***IPHISA ELEGANS* (Glossy Shade Lizard). ENDOPARASITES.** *Iphisa elegans* is known from parts of Bolivia, Brazil, Colombia, Ecuador, French Guiana, Guyana, Peru, and Surinam (Avila-Pires 1995. Lizards of Brazilian Amazonia (Reptilia: Squamata). Zoologische Verhandelingen 299:1–706). It occurs in leaf and palm litter (Vitt and de la Torre 1998. A Research Guide to the Lizards of Cuyabeno. Museo de Zoologia, Centro de Biodiversidas y Ambiente Pontifica Universidad Católica del Ecuador, Quito. 165 pp.). We know of no reports of helminths for *I. elegans*. The purpose of this note is to establish the initial helminth list for *I. elegans*.

Five *I. elegans* (mean SVL = 38.2 mm ± 13.4 SD, range = 26–59 mm) from the herpetology collection of the Sam Noble Museum (OMNH, The University of Oklahoma, Norman, USA) collected February 1966 (OMNH 36964–36966) and April 1996 (OMNH 36967, 36968) in Brazil, Acre State, (ca. 5.0 km N Porto Walter, 8.25861°S, 72.77694°W, WGS 84; elev. 198 m) were examined for helminths. The stomachs had been previously removed and were not available for examination. The small and large intestine were removed, opened, and examined under a dissecting scope. Only nematodes were found. They were removed, placed separately on microscope slides, cleared in a drop of lactophenol, cover slipped, and studied under a compound microscope. Found were two species of Nematoda, *Cosmocerca vrcibradici*, one each in the large intestines of OMNH 36963 and 36968 (prevalence, number infected/number examined × 100 = 40%) and *Oswaldocruzia vitti*, six and one in the small intestines, of OMNH 36965 and 36967, respectively, prevalence = 40%, mean infection intensity = 3.5 ± 3.5 SD. Helminths were deposited in the United States National Parasite Collection (USNPC), Beltsville, Maryland, USA, as *Cosmocerca vrcibradici* (USNPC 105758) and *Oswaldocruzia vitti* (USNPC 105759).

Cosmocerca vrcibradici was described from the gymnopthalmid *Prionodactylus eigenmanni* (currently *Cerosaura eigenmanni*) from Rondônia Province, Brazil (Bursey and Goldberg 2004. J. Parasitol. 90:140–145). Other hosts are in Goldberg et al. 2010 (Herpetol. Rev. 41:495–496). *Oswaldocruzia vitti* was described from *P. eigenmanni* from Amazonas Province, Brazil, by Bursey

and Goldberg (*op. cit.*). A partial host list is in Avila and Silva (2010. J. Venom. Anim. Tox. Trop. Dis. 16:543–572); additional hosts include *Arthrosaura reticulata* (Goldberg et al. 2010. Herpetol. Rev. 41:349–350), *Cercosaura ocellata* (Avila and da Silva 2011. Comp. Parasitol. 78:129–139), and *Plica plica* and *P. umbra* (Goldberg et al. 2009. Herpetol. J. 19:49–52). *Iphisa elegans* represents a new host record for *C. vrcibradici* and *O. vitti*.

We thank Jessa L. Watters (OMNH) for facilitating the loan.

***LAUDAKIA STELLIO* (Roughtail Rock Agama). PARENTAL CARE.** Parental behavior, in various forms, has been documented in both oviparous and viviparous squamate species (Somma 2003a. The Linnean 19:42–46). Among agamids, only a few species are known to express parental behavior, mostly defending broods (e.g., *Uromastyx acanthinura* and *Pseudotrapelus sinaitus*), social assistance (e.g., *Agama agama*) and parental care (e.g., *Leiolepis belliana*) of neonates (Mendelssohn and Bouskila 1989. Comparative Ecology of *Uromastyx aegyptius* and *Uromastyx ornatus* in Southern Israel and Southern Sinai. First World Congress of Herpetology, Univ. of Kent, Canterbury, UK. [abstract]; Somma 2003b. Parental Behavior in Lepidosaurian and Testudinian Reptiles. Krieger Publ. Co., Malabar, Florida. 174 pp.). We have recently observed a new form of parental treatment in the Roughtail Rock Agama (*Laudakia stellio*), a species for which parental care has never been documented in the past to our knowledge.

PHOTO BY: ZOHAR YANAI

FIG. 1. A) An adult *Laudakia stellio* observed standing at the nest chamber entrance; B) the egg found inside the nest chamber.

The observation took place during the late morning hours of summer 2010, in a private garden in Pardes Hanna, Israel (32.2755°N, 58.3418°E).An individual *L. stellio* (gender unknown) was observed coming out of a nest chamber dug in the soil (Fig. 1). The chamber, about 10 cm deep, was placed in an eolianite plot (also known as kurkar), a common soil type along the coastal plain of Israel. This chamber was located in the middle of a bare, plain flowerbed, in an area where human, canine, and avian activity commonly occurs. The agama entered the nest chamber and came out holding an egg in its mouth. The egg was white, oval, and approximately 2 cm long. While the agama was holding the former egg in its mouth, another one was left in the chamber (Fig. 2). Upon noticing the observer (ZY), the lizard hastily dropped the egg and ran away. A few minutes later, after the observer moved away, the lizard returned and transferred both eggs (the one deserted on the surface and the other left in the chamber) into a safer location between nearby bushes.

In Israel, agamid species are known to avoid bare, plain, and homogeneous habitats (e.g., Arbel 1984. Plants and Animals of the Land of Israel. Vol. 5: Reptiles and Amphibians. Ministry of Defense, Israel. 244 pp.; Bouskila and Amitai 2006. Handbook of Amphibians and Reptiles of Israel. 3rd ed. Keter Publishing House, Jerusalem. 345 pp.; Schleich et al. 1996. Amphibians and Reptiles of North Africa. Koeltz Scientific Publishers, Koenigstein. 629 pp.). Therefore, the flowerbed, characterized by these features (Fig. 1), was probably not an optimal nesting site and thus we assume that this individual preferred to move its eggs to a safer or more appropriate site.

In this report we present two novel observations. First, the eggs were relocated to a more favorable nest site—a type of behavior already reported (Somma 2003b, *op. cit.*) as ME (manipulation or retrieval of eggs) for other squamates (e.g., Anguidae), but has never been observed in agamids. Second, this is the first documentation of any parental behavior for *L. stellio*. However, we must take into consideration that this observation may have potentially been an example of intraspecific competition, in which an individual sabotages another individual's brood. This interpretation is less likely, because we assume that if that was the case, the eggs would have been consumed, rather than moved, by the observed individual.

ZOHAR YANAI (e–mail: yanai.zohar@gmail.com) and **LITAL DABOOL** (e-mail: litald2@gmail.com), Department of Zoology, Faculty of Life Sciences, Tel-Aviv University, Tel Aviv 69978, Israel.

***LEPIDOPHYMA MICROPHOLIS* (Cave Tropical Night Lizard). ENDOPARASITES.** *Lepidophyma micropholis* is known from San Luis Potosí and Tamaulipas, Mexico (Flores Villela and Gerez 1994. Biodiversidad y Conservacíon en México: Vertebrados, Vegetacíon uso del Suelo. Comision Nacional para el Conocimiento y Uso de la Biodiversidad y Universidad Nacional Autónoma de Mexico, Ciudad Universitaria, México, D.F. 439 pp.). The purpose of this note is to establish the initial helminth list for *L. micropholis*.

One *L. micropholis* female (SVL = 75 mm) from 8.6 km S of Valles, 2.0 km E of Hwy 89 (21.9877664°N, 99.0012607°W, datum WGS 84; elev. 2411 m) was collected in May 1981 and deposited in the Texas Cooperative Wildlife Collection (TCWC), Texas A&M University, College Station, Texas, USA as TCWC 59926. Four nematodes (1 male, 3 females) were visible through the wall of the large intestine. They were removed through a small incision in the intestinal wall, cleared in glycerol on a microscope slide, cover slipped, and studied under a compound microscope. Voucher helminths were deposited in the United States National Parasite Collection (USNPC), Beltsville, Maryland, USA.

The nematodes were identified as *Aplectana herediaensis* and were deposited as USNPC (104768). *Aplectana herediaensis* was described from *Lepidophyma flavimaculatum* from Costa Rica (Bursey et al. 2006. Carib. J. Sci. 42:164–170). It was later found in *L. flavimaculatum* from Panama (Bursey et al. 2007. Comp. Parasitol. 74:108–140). *Aplectana* is a cosmocercoid nematode with no intermediate host; infection occurs by ingestion of eggs (Anderson 2000. Nematode Parasites of Vertebrates. Their Development and Transmission. 2nd Ed. CABI Publishing, Wallingford, Oxon, UK. 650 pp.). *Lepidophyma micropholis* represents a new host record for *A. herediaensis*; Mexico is a new locality record.

We thank T. Hibbitts (TCWC) for permission to examine *Lepidophyma micropholis*.

STEPHEN R. GOLDBERG, Department of Biology, Whittier College, Whittier, California 90608, USA (e-mail: sgoldberg@whittier.edu); **CHARLES R. BURSEY,** Pennsylvania State University, Shenango Campus, Biology Department, Sharon, Pennsylvania 16146, USA (e-mail: cxb13@psu.edu).

***LEPIDOPHYMA MICROPHOLIS* (Cave Tropical Night Lizard). REPRODUCTION.** *Lepidophyma micropholis* is known from San Luis Potosi and Tamaulipas, Mexico (Flores Villela and Gerez 1994. Biodiversidad y Conservacíon en México: Vertebrados, Vegetacíon y uso del Suelo. Comision Nacional para el Conocimiento y uso de la Biodiversidad y Universidad Nacional Autónoma de Mexico. Ciudad Universitaria, México, D.F. 439 pp.). To my knowledge, there is no information on the reproduction of *L. micropholis*. The purpose of this note is to provide information on the reproductive cycle of *L. micropholis*.

A sample of 11 *L. micropholis* was examined, consisting of three adult males (mean SVL = 99.3 mm ± 5.5 SD; range = 93–103 mm), six adult females (mean SVL = 95.7 mm ± 5.3 SD; range = 88–100 mm), one subadult female (SVL = 75 mm), and one neonate (SVL = 28 mm), all collected in May 1981, from 8.6 km S of Valles, 2.0 km E of Hwy 89 (21.9877664°N, 99.0012607°W, datum WGS 84; elev. 2411 m) and deposited in the Texas Cooperative Wildlife Collection (TCWC), Texas A&M University, College Station, Texas, USA as: TCWC 59923–59926, 59962, 59963, 59965, 59975, 59976, 60766, 60767.

One gonad from each *L. micropholis* was removed for histological examination except for gravid females in which enlarged ovarian follicles (> 5 mm), oviductal eggs, or embryos were counted. Tissues were embedded in paraffin, sections cut at 5 µm, and stained by Harris hematoxylin, followed by eosin counterstain. Histology slides were deposited in TCWC.

Like other xantusiids, *L. micropholis* is viviparous (Vitt and Caldwell 2009. Herpetology, 3rd ed. Academic Press, Elsevier, Amsterdam. 697 pp.). All six adult female *L. micropholis* were gravid (mean litter size = 5.3 ± 2.7 SD, range = 3–10) with parturition due in late spring or, perhaps, early summer. One subadult female was not reproductively active. One neonate *L. micropholis* was collected in May. This agrees with the timing of parturition in other species of *Lepidophyma* (Goldberg 2009. Phyllomedusa 8:59–62). Testes of male *L. micropholis* were regressed, with seminiferous tubules containing spermatogonia. Whether the timing of sperm production in *L. micropholis* is consistent with other congeneric species in which spermiogenesis occurs in summer or autumn (Goldberg, *op. cit.*) will require histological examination of *L. micropholis* testes from this period.

I thank T. Hibbitts (TCWC) for permission to examine *L. micropholis*.

STEPHEN R. GOLDBERG, Department of Biology, Whittier College, Whittier, California 90608, USA; e-mail: sgoldberg@whittier.edu.

***PETROSAURUS THALASSINUS* (San Lucan Banded Rock Lizard). LIMB REGENERATION.** One of the most well-known predator defense mechanisms employed by lizards is tail autotomy, accompanied by tail regeneration (Pianka and Vitt 2003. Lizards, Windows to the Evolution of Diversity. University of California Press, Berkeley. 333 pp.). However, limb regeneration can occur, and has been observed in such genera as *Lacerta*, *Liolaemus*, and *Sceloporus* (Bellairs and Bryant 1985. *In* C. Gans and F. Billett [eds.], Biology of the Reptilia, Vol. 15, Development B, pp. 387–392. John Wiley & Sons, New York), and *Ctenosaura* (Pasachnik 2011. Herpetol. Rev. 42:600). There are no reports of limb regeneration in lizards of the genus *Petrosaurus*.

We captured a sub-adult female *P. thalassinus* (SVL: 87 mm, TL: 98 mm, 17 g) on 14 April 2012, at El Chorro, 3.40 km W of Agua

FIG. 1. *Petrosaurus thalassinus* with a partially regenerated hind limb observed at El Chorro, Agua Caliente, Baja California Sur, México.

Caliente, Baja California Sur, México (23.43949°N, 109.80876°W; WGS84; 204 m. elev.). The left hind limb of the individual appeared to be regenerated and looked much more like that of a regenerated tail (Fig. 1). In some lizard species, the hind limbs are longer and typically more robust than the fore limbs, providing most of the propulsive force during locomotion (Pough et al. 2004. Herpetology, 3rd ed. Prentice Hall, Upper Saddle River, New Jersey. 726 pp.); nevertheless this individual did not seem to be disadvantaged by its deformity, as it was observed to climb and run like a normal *Petrosaurus*. A photo image was deposited in the La Sierra University Digital Photo Collection (LSUHCDPC 6331) and Centro de Investigaciones Biológicas del Noroeste Herpetological Collection (CIB 1476).

RUBÉN ALONSO CARBAJAL-MÁRQUEZ (e-mail: redman031@hotmail.com) and **JORGE H. VALDEZ-VILLAVICENCIO** (e-mail: j_h_valdez@yahoo.com.mx), Centro de Investigaciones Biológicas del Noroeste, Mar Bermejo, Colonia Playa Palo de Santa Rita No., C.P. 23090, La Paz, Baja California Sur, México.

***PLESTIODON EGREGIUS* (Mole Skink). MATING ACTIVITY.** Unlike most lizards native to the southeastern United States, Mole Skinks typically have peak courtship and mating activity during the cooler months of fall and winter (Mount 1963. Amer. Midl. Nat. 70:356–385). Mount (*op. cit.*) reported the onset of mating at his Levy Co., Florida study site as "sometime during September and October," and that sexually active male Mole Skinks were collected from the Fall Line Hills region of Georgia in September.

On a late summer afternoon (28 August 2009; high temperature for the day: 27°C), at Fall Line Sandhills Wildlife Management Area, Taylor Co., Georgia, USA (32.570384°N, 84.407161°W), we observed an adult male Mole Skink that had seized an adult female Mole Skink in his jaws, just posterior to her front left leg (Fig. 1). Although we did not observe actual mating, biting and seizure of the female by the male in her anterior trunk region is characteristic of previously documented courtship immediately prior to mating (Mount, *op. cit.*). We believe this represents the earliest report of mating in this species and the only occurrence of such activity during summer.

Additionally, due to the clear vulnerability Mole Skinks would present to potential predators while copulating, and because he never observed sexual activity of this species in the wild, Mount (*op. cit.*) suggested that perhaps *P. egregius* normally mates in sheltered situations such as inside Gopher Tortoise (*Gopherus polyphemus*) burrows and Southeastern Pocket Gopher (*Geomys pinetis*) tunnels. While that may indeed be the norm, the pair we observed were highly exposed on the surface in the middle of a sandy, vegetation-free road; the adjacent habitat was open-canopied xeric sandill dominated by Turkey Oak (*Quercus laevis*) and Longleaf Pine (*Pinus palustris*).

STEVENSON**, The Orianne Society, Indigo Snake Initiative, 414 Club Drive, Hinesville, Georgia 31313, USA (e-mail: dstevenson@oriannesociety.org).

***PLESTIODON INEXPECTATUS* (Southeastern Five-lined Skink). BIFURCATION.** Caudal bifurcation is considered to be a common phenomenon in lizards (Kumbar and Ghadage 2011. Herpetol. Rev. 42:94 and references therein; Mata-Silva et al. 2010. Herpetol. Rev. 41:352; Smith 1946. Handbook of Lizards of the United States and Canada, Cornell Univ. Press, Ithaca, New York. 557 pp.). Skinks seem especially prone to tail loss, regeneration, and bifurcation, and several permutations have been published and illustrated (e.g., Scott 1982. Herpetol. Rev. 13:46; Taylor 1935. Univ. Kansas Sci. 23:1–643; Walley 1997. Bull. Maryland Herpetol. Soc. 33:178–180). Here we describe an extreme example of caudal bifurcation in *P. inexpectatus*.

On 17 March 2012, we observed an adult female *P. inexpectatus* with two tails on a suburban porch in Davenport, Polk Co., Florida, USA (28.205522°N, 81.567944°W; NAD 84). The lizard was observed frequently over a period of several weeks. The bifurcation occurred at the base of the tail and resulted in two tails of approximately the same diameter and length (Fig. 1). Based on pattern and scalation, the left tail appeared to be the original one with the regenerated right tail articulating with the original immediately posterior to the cloaca. In addition, the left tail appears to have been broken just distal to the base with subsequent regeneration and again about 1.5–2 cm distally from that breakage plane with additional regeneration. This is the first report of caudal bifurcation in *P. inexpectatus* from Florida.

JOSEPH C. MITCHELL, P.O. Box 2520, High Springs, Florida 32655-2520, USA (e-mail: dr.joe.mitchell@gmail.com); **WILLIAM McDANIEL** and **JENNYFER McDANIEL**, Davenport, Florida 33837, USA.

FIG. 1. Courtship by male *Plestiodon egregius* biting and seizing female, Taylor Co., Georgia, USA.

FIG. 1. A female *Plestiodon inexpectatus* from Polk Co., Florida, expressing caudal bifurcation.

***PLESTIODON MULTIVIRGATUS* (Many-lined Skink). ENDOPARASITES.** *Plestiodon multivirgatus* is known from southern South Dakota to west Texas and Chihuahua, Mexico through New Mexico to southeastern Utah and central Arizona where it lives in a variety of habitats from 910 to ca. 2620 m elev. (Lemos Espinal and Smith 2007. Amphibians and Reptiles of the State of Chihuahua, Mexico. Universidad Nacional Autónoma de México. Los Reyes Iztacala Tlalnepantla, Edo. de México, México. 613 pp.; Stebbins 2003. A Field Guide to Western Reptiles and Amphibians. Houghton Mifflin, Boston, Massachusetts. 533 pp.). We know of no helminth records for *P. multivirgatus*. The purpose of this note is to establish the initial helminth list for *P. multivirgatus*.

The coelomic cavity of one male *P. multivirgatus* (SVL = 58 mm) collected in Bernalillo Co., New Mexico, USA in August 1949 and deposited in the herpetology collection of the County Natural History Museum of Los Angeles County (LACM), Los Angeles, California, USA, as LACM 14912 was examined.

The body cavity was opened and visually examined for helminths. One oval shaped whitish endoparasite ca. 2 mm in length was found. It was studied under a dissecting microscope. Based on body shape, pseudoannulation, and hook root morphology it was identified as an oligacanthorhynchid acanthocephalan cystacanth. It was deposited in the United States National Parasite Collection, Beltsville, Maryland, USA, as USNPC 105791.

Acanthocephalans require an arthropod intermediate host in which the cystacanth develops (Kennedy 2006. Ecology of the Acanthocephala. Cambridge University Press, Cambridge, UK. 249 pp.). Lizards become infected by ingesting an infected insect. Development to the adult acanthocephalan occurs when the infected lizard is eaten by a definitive host. Because the cystacanth does not develop in the lizard, they likely serve as paratenic (transport) hosts. *Plestiodon multivirgatus* represents a new host record for oligacanthorhynchid cystacanths.

We thank Christine Thacker (LACM) for permission to examine *P. multivirgatus*.

STEPHEN R, GOLDBERG, Department of Biology, Whittier College, Whittier, California 90608, USA (e-mail: sgoldberg@whittier.edu); **CHARLES R. BURSEY,** Department of Biology, Pennsylvania State University, Shenango Campus, Sharon, Pennsylvania 15146, USA (e-mail: cxb13@psu.edu).

***SCELOPORUS CLARKII* (Clark's Spiny Lizard). BODY TEMPERATURE.** *Sceloporus clarkii* is a medium-large arboreal lizard that inhabits a wide variety of habitats, from sea level to about 1840 m (Stebbins 2003. A Field Guide to Western Reptiles and Amphibians. 3rd ed. Houghton Mifflin, New York. 533 pp.). Little is known about ecology of this lizard, and even less about the thermal ecology within island populations. Here we present data on *S. clarkii* thermal ecology from Isabel Island, México.

During 15–17 April 2008, we conducted fieldwork in the Parque Nacional Isla Isabel (PNII) off the coast of Nayarit, México (21.84699°N, 105.88447°W, elev. 20 m, datum: WGS84). PNII is a small volcanic island dominated by tropical deciduous forest vegetation (e.g., *Crataeva tapia* and *Euphorbia schlechtendalii*), grasses, and volcanic rocks (CONANP 2005. Programa de Conservación y Manejo Parque Nacional Isla Isabel. México. 164 pp.). Data are based on 33 captures (12 females and 21 males) made between 800 and 1800 h on sunny days. Adult individuals were captured by noosing. For each capture, we measured body temperature (T_b) and air temperature (T_a) with a thermocouple of a quick-reading thermometer (Fluke 52 K/J type), and substrate temperature (T_s) with non-contact infrared thermometer (EXTECH instruments, Model 42529 ± 1°C). We took T_s at the exact point where the animal was first sighted and T_a 2 cm above the substrate, both immediately following capture. We also recorded snout vent length (SVL), sex, activity time, microhabitat type and perch light (full sunlight, filtered sunlight and full shade) for each individual.

Mean SVL was 78.6 mm (SD = 10.4, range: 57–99 mm, N = 33). Mean body temperature was 33.7°C (SD = 2.7, range: 26.9–36.6°C). No significant differences in T_b were found between sexes (t-Student, t = 1.4, $P = 0.17$). Mean air temperatures was 25.2°C (SD = 1.2, range: 23.4–28.5°C). Mean substrate temperatures was 33.1°C (SD = 3.8, range: 25–43°C). Body size did not have a significant influence on T_b (Spearman Rank Correlation, $r_s = -0.34$, $P>0.06$). Body temperature and T_s were significantly correlated (Spearman Rank Correlation, $r_s = 0.65$, $P < 0.0001$), but T_b and T_a were not (Spearman Rank Correlation, $r_s = 0.11$, $P > 0.05$). Most lizards were found on trees (N = 20), followed by rocks (N = 12), and ground (N = 1); and perched more frequently in full sunlight microhabitats (N = 19), followed by full shade (N = 9) and filtered sunlight (N = 5).

The positive correlation between T_b and T_s supports the well-known fact that *S. clarkii* is a thigmothermic species that gains heat by moving between substrates with different sunlight categories. This species presents a mean body temperature found within the range for other *Sceloporus* species: 28.6–37°C (Andrews 1998. J. Therm. Biol. 23[6]:329–334). Compared with other *Sceloporus* species on islands in the Gulf of California, the mean T_b for *S. clarkii* was lower (e.g., *S. orcutti* = 34.5°C and *S. grandaevus* = 35.7°C; Soulé 1963. Copeia 1963:107–115).

***SCELOPORUS VARIABILIS* (Rose-bellied Lizard). PREY.** On 28 January 2012 just south of Playa Gigante, Departamento de

PHOTO BY M. E. BABCOCK

FIG. 1. Predation of a juvenile *Aspidoscelis deppii* by an adult male *Sceloporus variabilis*.

Rivas, Nicaragua (11.38279°N, 86.02512°W; WGS84), one of us (MF) observed and photographed an adult male *Sceloporus variabilis* predating a juvenile *Aspidoscelis deppii*. The juvenile whiptail was being consumed head-end first. The entire predation event took about 10 minutes. These two species commonly co-occur in arid habitats in Central America (Köhler 2008. Reptiles of Central America. Herpeton. Offenbach, Germany. 400 pp.). *Sceloporus variabilis* is known to feed on a variety of insects and other arthropods (Fitch 1973. Univ. Kansas Sci. Bull. 50:39–126; Savage 2002. The Amphibians and Reptiles of Costa Rica: A Herpetofauna between Two Continents, between Two Seas. Univ. Chicago Press. Chicago, Illinois. 934 pp.). This is the first published account of saurophagy in *S. variabilis*.

***TILIQUA ADELAIDENSIS* (Pygmy Bluetongue Lizard). ALTERNATE REFUGE.** Suitable refuges can be critical for most animal species because they provide protection from predators and climate extremes (Grillet et al. 2010. Biodiv. Conserv. 19:2039–2051). Some species can construct their own shelters while others rely on burrows or structures built by other animals (Kotler et al. 2004. Ecology 85:917–922). The distribution of an animal is thus highly dependent on the availability of refugia and distribution of the refuge building species (Souter et al. 2004. Biol. Conserv. 116:403–408). One example is an endangered scincid lizard from South Australia, *Tiliqua adelaidensis*. This lizard normally uses burrows built by lycosid and mygalomorph spiders. The lizard uses these burrows as refuges, and basks at the burrow entrances, ambushing passing invertebrate prey (Fig. 1) (Milne et al. 2003. Wildl. Res. 30:523–528). Lizards of this species prefer deeper burrows (>30 cm in depth) (Fig. 2) with entrance diameters slightly wider than their head width (average 15.1 mm) (Milne and Bull 2000. Biol. Conserv. 95:295–301). In this note we describe observations of an alternate natural burrow system that can be used by *T. adelaidensis* and that might increase the range of options for the optimal management of existing populations, and for the possible selection of translocation sites.

On 25 October 2009, we moved eight male and eight female *T. adelaidensis* into four 15-m diameter circular cages in Monarto Zoo (35.10°S 139.15°E) approximately 70 km SE of Adelaide, South Australia. The cages had galvanized iron walls, 1 m high, that were buried 15 cm under the ground surface. Two male and two female lizards were released into each cage. There were no natural burrows in the cages initially. Instead we constructed artificial burrows from 30 cm lengths of wooden dowling with a drilled out center of 2 cm internal diameter (Fig. 3). Previous studies have shown *T. adelaidensis* accept and use these artificial

FIG. 1. Pygmy Bluetongue Lizard basking at the entrance of a natural burrow.

FIG. 2. A natural burrow built by a lycosid spider.

FIG. 3. A) Pygmy Bluetongue Lizard feeding at the entrance of an artificial burrow; B) an artificial burrow.

FIG. 4. A mouse hole.

burrows (Milne et al. 2003. J. Herpetol. 37:762–765; Souter et al., *op. cit.*). Seventy-one artificial burrows were hammered vertically into the ground in each cage. Experiments, set up to measure the responses of the lizards to various environmental conditions in the cages, are reported elsewhere (Ebrahimi and Bull 2012. Trans. Royal Soc. S. Australia 136:45–49; Ebrahimi et al. 2012. Wildl. Res. 39:295–300). We inspected each cage daily and removed any mice (*Mus musculus*) that had burrowed under the cage wall, and filled in any burrows they had made (Fig. 4). During two lizard seasons at Monarto Zoo we caught 57 mice (35 in 2009–2010; 22 in 2010–2011) inside the cages. Ninety mouse holes were composed of short tunnels under the cage walls with one entrance inside and the other outside the cage. Fourteen mouse nests were found within the cages (10 in the first season; 4 in the second season) with one or two entrances inside the cages. Two of those nests were unoccupied when discovered, but 10 nests were found with a single mouse, and two had two mice. In the 2010–2011 lizard season the average diameter of 40 mouse hole entrances was 2.14 ± 0.016 cm. We found two male lizards, in the second season at Monarto, one on 22 December 2010 and the other on 27 January 2011, basking at the entrance of mouse holes inside a cage while other lizards basked at the entrance of artificial burrows. Both lizards were caught and released back into the central area of the cage, and the entrance diameters of the mouse holes were measured (each was 2.0 cm) as they were destroyed. We did not find any mice inside these burrows. One of the mouse burrows was 85 cm long and 25.5 cm below the ground at its deepest point. It had an enlarged underground chamber and another entrance outside the cage. The other was 95 cm long, 35 cm deep, had two enlarged chambers, and had a second entrance (2.2 cm diameter) inside the cage. The two entrances of this second mouse hole were about 80 cm apart. We could not prolong our observations of the lizards in these alternative refuges because we needed to prevent them escaping from their enclosures.

Other observations were conducted over the lizard season of 2009–2010, in three 1-ha^2 areas within a natural population of *T. adelaidensis* located 9 km from Burra (33.683°S 138.933°E), South Australia. Fences and pitfall traps were established around each area (15 cm high black plastic drift fencing; 16 pitfalls, each 30 cm diameter and 40 cm deep placed along each side of each 1-ha quadrat), as part of a study of lizard population dynamics. We used an Olympus IF8D4X2-10L optic fiber scope to inspect each natural burrow within each area for burrow residents. Among the lizard captures we also trapped 90 mice in the pitfalls and we located and measured the entrance diameter (3.15 ± 0.14 cm) of 19 mouse holes within the study quadrats. Two mouse holes had 2.2 cm diameter entrances, within the range of entrance diameters preferred by adult lizards (Milne and Bull 2000, *op. cit.*). The fiberscope had a functional length of 35 cm, and each of the mouse holes extended beyond that length. Thus we could not determine if any mouse holes were occupied by lizards. Nevertheless, mice provided burrows that may have provided alternative refuges for *T. adelaidensis* in a natural field population. Many studies that have noted the importance of rocks, logs, rodent burrows, cervices, dead leaves, and thick bushes as a potential shelter sites for squamate reptiles (Grillet et al. 2010, *op. cit.*; Webb and Shine 2000. Biol. Conserv. 92:93–99), but some species are more specific in their choice of refugia. Previous reports have suggested that *T. adelaidensis* uses only spider burrows (Hutchinson et al. 1994. Trans. Royal Soc. S. Australia 118:217–226). Our observations in this report indicate this lizard will use another kind of shelter, in the form of mouse tunnels.

MEHREGAN EBRAHIMI (e-mail: mehregan.ebrahimi@gmail.com), **JULIE A. SCHOFIELD**, and **C. MICHAEL BULL**, School of Biological Sciences, Flinders University, GPO Box 2100, Adelaide, South Australia 5001, Australia.

***VARANUS GOULDII* (Sand Monitor) and *VARANUS PANOPTES* (Yellow-spotted Monitor). PREDATION.** Identifying trophic links is critical to understanding multiple areas of ecology, including food webs, predator-prey dynamics, and the impacts of invasive species. In tropical areas trophic links are often unknown or putative, and this is true of the Australian wet-dry tropics.

Varanus gouldii is a moderate-sized lizard (up to 1.6 m in total length) that inhabits adjacent open savannah, as well as sandhills, rocky areas, and desert habitats across much of Australia (Cogger 2000. Reptiles and Amphibians of Australia. Reed New Holland, Sydney. 808 pp.). *Varanus panoptes* is a larger-bodied species (up to 1.5 m in total length) inhabiting riparian areas and floodplains in tropical Australia (Cogger 2000, *op. cit.*). Although few predators are large enough to prey upon these species as adults, eagles are an exception. Herein we report monitor lizard predation by two Australian eagle species, based on prey item surveys at eagle nests, and an observation of predation near a nest at five sites in Western Australia (WA). We discuss the importance of monitor lizards as prey for eagles, and implications for the declines in monitors with the arrival of invasive Cane Toads (*Bufo marinus*) in northern WA.

On 16 May 2011 a male White-bellied Sea Eagle (*Haliaeetus leucogaster*) was observed feeding on a large (>40 cm SVL) *V. panoptes* near its nest at the junction of the Chamberlain and Pentecost rivers at El Questro Wilderness Park in the Kimberley Region (15.968847°S, 127.928739°E). The eagle carried the lizard between two high tree perches within 100 m of the nest. The sex of the lizard could not be determined, but based on size it was either a small adult male or a large adult female. The nest was ca. 30 m high in a *Eucalyptus* tree. On 27 May the nest tree was climbed, revealing two eggs, and both the male and female were seen repeatedly near the nest between the date of discovery and the date climbed. Prey remains under nest and perch trees included two individuals of the Northwest Red-faced Turtle, *Emydura australis*, a flying fox (*Pteropus* sp.), and various fish scales. Although it is possible that the eagle found the lizard as carrion, the prey item was well within the prey-size range of the raptor.

The contents of three Wedge-tailed Eagle (*Aquila audax*) nests near a breakaway (butte) on Mileura Station in the Murchison-Gascone Region of Western Australia (26.412168°S, 117.199255°E) were examined in June 2010, following breeding events in 2008 and 2009. Prey remains were analyzed by comparison to a reference collection of skeletal material and the number and species of prey animals identified. Data from the 2008 breeding event at one nest indicated the eagles had fed upon one large (>40 cm SVL) *V. panoptes*, as well as seven juvenile Euros (*Macropus robustus*) and two juvenile Feral Goats (*Capra hircus*). Data from two nests representing 2009 breeding diet revealed a total of eight monitor lizards: two *V. panoptes* from one nest and six unidentified varanids (either *V. panoptes* or *V. gouldii*) from the second nest, all having SVL of >40 cm. Other remains identified were those of juvenile *Macropus* spp. (N = 15), Feral Goats (N = 8), European Rabbit (*Oryctolagus cuniculus*) (N = 2), and a nestling Australian Kestrel (*Falco cenchroides*) (N = 1).

Another study in similar habitat conducted during October 2011 aimed to research potential impacts of eagles preying on reintroduced threatened mammals at a conservation reserve. Twenty-six individual animals were identified as eagle prey from a single 2011 breeding event at a single *A. audax* nest. Of these, five were monitor lizards (either *V. panoptes* and/or *V. gouldii*, based on location). Based on size, two of the monitors identified from large vertebrae and large claws were almost certainly *V. panoptes*, having an approximate SVL of >50 cm.

Two *A. audax* nests belonging to the same breeding pair of eagles were located near Chidlow in the Perth Hills Region (31.862433°S, 116.269298°E). The nests were climbed in two separate breeding years to examine food items in a study investigating the number of mammal species consumed at the edge of a wildlife sanctuary containing endangered species. In 2004, the carcass of one *V. gouldii* was identified at one nest, and in 2005 at the second nest, another single *V. gouldii* was noted. The total size and sex of these animals was unknown but the size of the vertebrae of the first individual indicated it was probably >30 cm SVL. Most other items observed in the nests were those of mammals and birds which formed a greater portion of eagle diet in this closed forest habitat (Cherriman 2007. Honours Thesis, Curtin University, Perth).

Dietary remains were collected from three *A. audax* nests within 25 km from the town of Narrogin in the Narrogin Region (32.931075°S, 117.179317°E) by an officer from the Department of Environment and Conservation of Western Australia, and sent to S. Cherriman for identification. These items represented breeding diet from 2006 and 2007. A total of five individual varanids (either *V. gouldii* and/or *V. rosenbergi*) were identified in the sample, one of which had a SVL <40 cm. Other prey animals eaten at all three nests included *Macropus* spp. (N = 71), rabbits (N = 49), birds (N = 29), Common Brushtail Possums (*Trichosurus vulpecula*) (N = 19), sheep (N = 10), skinks (N = 8), and agamid spp. (N = 3).

Both eagle species are previously unreported predators of *V. panoptes*, while *A. audax* has been reported to prey upon *V. gouldi* and the Lace Monitor, *V. varius* (Brooker and Ridpatch 1980. Austral. Wildl. Res. 7:433–452; Leopold and Wolfe 1970. Austral. Wildl. Res. 15:1–17). The lack of *V. panoptes* as a reported prey item for these species probably reflects the dearth of dietary studies in tropical Australia, rather than an infrequent trophic interaction. Large monitor lizards such as *V. gouldii* and *V. panoptes* are apparently important prey items for these eagles (Brooker and Ridpath 1980, *op. cit.*; Silva and Croft 2007. Corella 31:23–31). *Varanus panoptes* is one of three species of Australian monitor lizards that suffer severe population-level declines, via lethal toxic ingestion, with the invasion of *Bufo marinus* (e.g., 83–96%, Doody et al. 2009. Anim. Conserv. 12:46–53). Other Australian monitor lizard species such as *V. gouldii* also die when trying to consume *B. marinus*, although the effect on populations has not been quantified. In the case of severe population declines in *V. panoptes*, invading Cane Toads are essentially removing an important prey item for at least sea eagles, potentially influencing the energetics and reproductive success of these apex predators. At the very least we predict a significant shift in the diet in sea eagles as a result of toad invasion and declines in *V. panoptes*. Since the toad has not yet invaded most of the Kimberley Region, but is likely to do so within the next decade, dietary surveys of eagle nests before and after toad invasion in the Kimberley Region would test this prediction.

J. SEAN DOODY, The Orianne Society, 579 Hwy 441 South, Clayton, Georgia 30525, USA (e-mail: sdoody@oriannesociety.com); **SIMON CHERRIMAN**, 180 Glendower St., Parkerville, 6081, Western Australia (e-mail: aquila84@iinet.net.au).

SQUAMATA — SNAKES

***BOA CONSTRICTOR* (Boa Constrictor). AQUATIC HABITAT USE.** *Boa constrictor* is a large arboreal and terrestrial boid with a broad geographic distribution extending from northern Mexico into South America as far as Peru, Argentina, and Uruguay (McCranie 2011. The Snakes of Honduras. Systematics, Distribution, and Conservation. SSAR, Ithaca, New York. x + 714 pp.). On 28 April 2011, we visited Pedernales, a small village on the southwestern shore of Lago de Yojoa, in Santa Bárbara, Honduras (14.814194°N, 88.010750°W, datum WGS84; elev. 650 m). We inquired about snakes from several members of a crew of workers who were removing dense growths of the introduced water hyancinth (*Eichhornia crassipes*) from the lake. Two of those workers quickly produced a small (total length = 943 mm) dead *B. constrictor* (UNAH 5652) that they had killed that morning. According to the workers, the *B. constrictor* was coiled in the water hyacinths and partially submerged in the lake when it was found. The same workers also showed us a similarly-sized decomposing *B. constrictor* they had found in a similar situation several days earlier. Those two snakes were killed at the height of the dry season. Perhaps the boas had chosen the water hyacinth mats as a refuge from the mostly open and dry deforested surroundings of the lake. McCranie (*op. cit.*) reported finding boas submerged in a small stream and a shallow river in Honduras, but those situations were in primary humid lowland rainforest.

JAMES R. McCRANIE, 10770 SW 164th Street, Miami, Florida 33157–2933, USA (e-mail: jmccrani@bellsouth.net); **LEONARDO VALDÉS ORELLANA**, Gerente General de "Hondufauna," Investigador Privado, Colonia América, Bloque 9, Casa 1806, Comayagüela, MDC, Honduras (e-mail: leovalor@hotmail.com).

***BOA CONSTRICTOR* (Boa Constrictor). DIET.** Diet is one of the most heavily studied aspects of snake ecology. Though strictly carnivorous, snakes feed on a wide variety of prey and may be dietary specialists or generalists. On 13 January 2006, a wounded juvenile *Boa constrictor* (SVL = 438 mm; tail length = 52 mm) was found near a group of Mango Trees on Pici Campus, Fortaleza, Ceará, Brazil. Dissection of the stomach revealed a bird, *Troglodytes musculus* (Southern House Wren or Rouxinol; 110 mm in length) (Fig. 1). Previous studies of *B. constrictor* indicate that

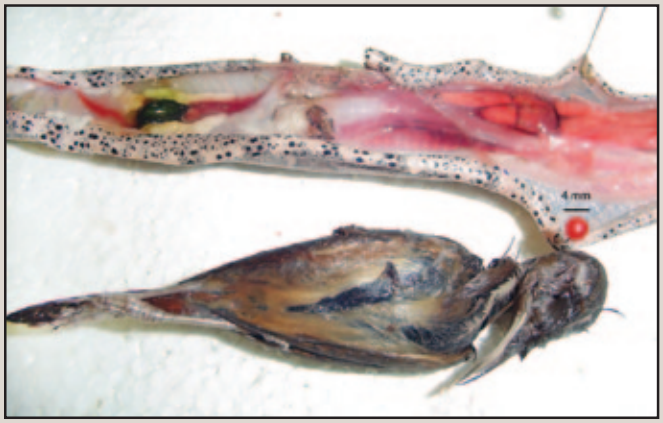

FIG. 1. *Troglodytes musculus* (Southern House Wren) recovered from the stomach of a juvenile *Boa constrictor* from Brazil.

this species is a dietary generalist, including mammals, reptiles, and especially birds as prey (Boback et al., 2000. Herpetol. Rev. 31:244–245; Greene 1997. Snakes: The Evolution of Mystery in Nature. Univ. California Press, Berkeley. 351 pp.; Quick et al. 2005. J. Herpetol. 39:304–307). This observation represents the first case of predation on *T. musculus* by *B. constrictor*. Both specimens are deposited in the herpetological collection, Núcleo Regional de Ofiologia, Universidade Federal do Ceará (CHUFC 2629).

PATRÍCIA DE MENEZES GONDIM (e-mail: patriciamg2003@yahoo.com.br), **DIVA MARIA BORGES-NOJOSA** (e-mail: dmbnojosa@yahoo.com.br), and **MARIA JULIANA BORGES-LEITE,** Núcleo Regional de Ofiologia da UFC, Departamento de Biologia, Universidade Federal do Ceará, Campus do Pici, Bloco 905, CEP 60.455-670, Fortaleza, Ceará, Brazil; **CIRO GIMENEZ ALBANO,** AQUASIS, Praia de Iparana, S/N, CEP: 61.600-000, Caucaia, Ceará, Brazil.

BOGERTOPHIS ROSALIAE **(Baja California Rat Snake). REPRODUCTION.** *Bogertophis rosaliae* occurs in the Peninsular Ranges from Imperial Co., California south to Cabo San Lucas, Baja California Sur, Mexico (Grismer 2002. Amphibians and Reptiles of Baja California Including its Pacific Islands and the Islands in the Sea of Cortés. Univ. California Press, Berkeley. 399 pp.). The purpose of this note is to add information on the reproductive biology of *B. rosaliae*.

Specimens were examined from the herpetology collections of the Natural History Museum of Los Angeles County (LACM), Los Angeles, California, Museum of Vertebrate Zoology (MVZ), University of California, Berkeley, California, and the San Diego Society of Natural History (SDSNH), San Diego, California. A portion of the left testis and vas deferens was removed from two males and a portion of the left ovary was removed from one female, embedded in paraffin, cut into 5-µm sections and stained with Harris hematoxylin followed by eosin counterstain. Histology slides were deposited at LACM, MVZ, and SDSNH.

One male (LACM 126095) collected DOR on 10 June 1977 from San Ignacio, Baja California Sur measured 1229 mm SVL. The testes were autolytic and could not be interpreted. The vas deferens contained abundant sperm. A second male (MVZ 10672) collected 11 April 1927 at San Ignacio, Baja California Sur measured 933 mm SVL. The germinal epithelium of the seminiferous tubules was greatly reduced in size and contained only 3-4 layers of cells. There were occasional small and widely separated clusters of sperm, suggesting they were residuals left over from a full spermiogenesis during the previous autumn. The vas deferens contained abundant sperm. The presence of the second male with markedly reduced germinal epithelium and a male (LACM 126095) with abundant sperm in the vasa deferentia may support *B. rosaliae* breeding in the spring as suggested by Grismer (*op. cit.*). One female (SDSNH 68737) collected 19 October 1997 from Arroyo San Gregorio, Baja California Sur measured 1020 mm SVL. The ovarian follicles contained oocytes with vacuoles but no yolk granules. Large coelomic fat deposits were present. It is likely eggs would have been produced the following spring. Ottley and Jacobsen (1983. J. Herpetol. 17:189–190) reported a gravid female collected in May.

We thank Christine R. Thacker (LACM), Bradford Hollingsworth (SDSNH), and Carol Spencer (MVZ) for permission to examine *B. rosaliae*.

STEPHEN R. GOLDBERG, Whittier College, Department of Biology, PO Box 634, Whittier, California 90608, USA (e-mail: sgoldberg@whittier.edu); **CLARK R. MAHRDT,** Department of Herpetology, San Diego Natural History Museum, San Diego, California 92102, USA (e-mail: leopardlizard@cox.net).

BOIGA IRREGULARIS **(Brown Treesnake). DIET.** The extirpation of Guam's native forest avifauna has been attributed to the accidental introduction of *Boiga irregularis* (Savidge 1987. Ecology 68:660–668). *Boiga irregularis* preys primarily on lizards as juveniles and on birds and mammals as adults; this pattern has been observed both in the native range (Shine 1991. Copeia 1991:120–131) and in the introduced population on Guam (Savidge 1988. J. Herpetol. 22:275–282). However, since the collapse of endothermic prey populations on Guam, the weight of predation has fallen more heavily on lizards (Rodda and Fritts 1992. J. Herpetol. 26:166–174). Since 2000, several anuran species have accidentally been introduced to Guam, potentially constituting an additional food source for invasive *B. irregularis* (Christy et al. 2007. Pac. Sci. 61:469–483). However, actual observations of *B. irregularis* predation upon frogs have been scarce.

During a visual survey at 1946 h on 3 October 2011, an adult male *B. irregularis* (SVL = 1062 mm; 105 g), was observed preying upon an adult female *Polypedates megacephalus* (SVL = 77.2 mm; 22.9 g) while perched 0.1 m above the ground on a branch of *Scaevola sericea*. The snake was initializing ingestion over the head of the prey when encountered, but abandoned ingestion when disturbed by the observers. The snake was found within limestone forest habitat on the Ordnance Annex of Naval Base Guam (13.37535°N, 144.67374°E; datum WGS 84). *Polypedates megacephalus* is naturally distributed in southern China, Taiwan, Tibet, and northern India (Zhao and Adler 1993. Herpetology of China. SSAR, Oxford, Ohio. 522 pp.) and was initially detected breeding in southeastern Guam in 2004 (Christy et al., *op. cit.*). To date, this is the only known instance of predation on *P. megacephalus* by *B. irregularis* on Guam. Such observations provide information on *B. irregularis* feeding ecology and the role that invasive prey species may have in supporting invasive *B. irregularis* populations.

MATT COOK, Cherokee Services Group, Dynamac Corporation, United States Geological Survey, Dededo, Guam 96912, USA; e-mail: mjcook@usgs.gov.

BOTHROPOIDES ERYTHROMELAS **(Caatinga Lancehead). REPRODUCTION.** *Bothropoides erythromelas* is a small lancehead widely distributed in northeastern Brazil (Lira-da-Silva et al. 2009. Gaz. Méd. Bahia 79:7–20), occurring in arid and semiarid environments including tropical dry and deciduous forests,

rocky areas, undergrowth vegetation of terrestrial bromeliads and along river banks (Campbell and Lamar 2004. The Venomous Reptiles of the Western Hemisphere. Cornell Univ. Press, Ithaca, New York. 870 pp.). Little is known about reproduction in this species (Duarte and Zanotti 2005. Herpetol. Rev. 36:188–189; Lira-da-Silva et al. 1994. Rev. Bras. Zool. 11:187–193). Two gravid female *B. erythromelas* were captured in the municipality of Inajá, Pernambuco, Brazil (8.901667°S, 37.823889°W, datum WGS84; elev. 362 m). Both were kept in captivity at the Laboratory of Venomous Animals and Toxins of the Universidade Federal do Pernambuco, Recife, Brazil. The first snake (SVL = 430 mm, tail length = 70 mm, 55 g) was collected on 9 June 2011 and gave birth to three live neonates (SVLs = 170, 175, 156 mm; tail lengths = 30, 26, 20 mm; 4.0, 3.8, 3.7 g) on 4 January 2012. The second female (SVL = 500 mm; tail length = 60 mm; 95 g) was collected on 15 July 2011 and gave birth to seven live neonates (mean SVL 167.1 mm ± 2.5 SD, range 165–171 mm; mean tail length = 25.1 mm ± 3.8 SD, range 20–30 mm; mean mass = 3.6 g ± 0.2 SD, range 3.1–4.0 g). Our results are consistent with the idea that *B. erythromelas* parturition occurs between November and February (Almeida-Santos and Salomão 2002. *In* Schuett et al. [eds.], Biology of the Vipers, pp. 445–462. Eagle Mountain Publ., Eagle Mountain, Utah; Duarte and Zanotti, *op. cit.*; Lira-da-Silva et al., *op. cit.*), just prior to the onset of the rainy season. However, our data extend the reported litter sizes to range from 3 to 11 (Lira-da-Silva et al., *op. cit.*).

Prof. Moraes Rego, 1235 - Cidade Universitária, 50670-901, Recife, PE, Brazil.

***BOTHROPS MOOJENI* (Brazilian Lancehead). DIET.** *Bothrops moojeni* is a common semi-arboreal snake included in the *B. atrox* group and is found throughout the Cerrado domain in central and southeastern Brazil in open habitats, almost always associated to gallery forests (Wüster et al. 1996. Herpetologica 52:263–271; Wüster et al. 1999. Kaupia 8:135–144). The genus *Bothrops* is characterized by a generalist diet and ontogenetic shifts from ectothermic to endothermic prey (Martins et al. 2002. *In* Schuett et al. [eds.], Biology of the Vipers, pp. 307–328. Eagle Mountain Publishing, Eagle Mountain, Utah). Previous studies indicate that *B. moojeni* is mainly nocturnal and active during the hot and rainy months, preying mostly on mammals and frogs (Nogueira et. al. 2003. J. Herpetol. 37:653–659). At 1946 h on 11 October 2010, during fieldwork in the municipality of Sacramento (20.20°S, 47.12°W; datum WGS84), Minas Gerais state, southeastern Brazil, we observed an adult *B. moojeni* (SVL ca. 70 cm) feeding on an adult hylid frog, *Hypsiboas albopunctatus* (Fig. 1). The snake was at the margin of a stream in a swamp area, where many *H. albopunctatus* males were calling perched on vegetation. It was initiating ingestion of the frog, head first, and continued for seven more minutes, until the prey was consumed. This is the first record of *H. albopunctatus* as prey of *B. moojeni* and confirms the snake's opportunistic foraging behavior (Nogueira et al., *op. cit.*).

We are grateful to Fundação de Amparo à Pesquisa do Estado de São Paulo and Conselho Nacional de Desenvolvimento Científico e Tecnológico, for the fellowships conceded to BFF (FAPESP proc. #2011/00507-2) and RCN (CNPq proc. #130737/2010-0 and FAPESP proc. #2010/03656-6) and Mr. Gaspar, for permitting access to field sites. C.P.A. Prado acknowledges FAPESP (proc. # 2009/12013-4), CNPq, and PROPE/UNESP for financial support.

FIG. 1. *Bothrops moojeni* preying on *Hypsiboas albopunctatus* in southeastern Brazil.

Castellane, 14884-900, Jaboticabal, São Paulo, Brazil (e-mail: ferreto_74@hotmail.com); **RENATO C. NALI**, Pós-Graduação em Ciências Biológicas (área Zoologia), Universidade Estadual Paulista, Av. 24-A, 1515, 13506-900, Rio Claro, São Paulo, Brazil; **CYNTHIA P. A. PRADO**, Universidade Estadual Paulista, FCAV, Departamento de Morfologia e Fisiologia Animal, Via de Acesso Prof. Paulo D. Castellane, 14884-900, Jaboticabal, São Paulo, Brazil.

***BOTHROPS PICTUS* (Desert Lancehead) and *PSEUDALSOPHIS ELEGANS* (Elegant Racer). PREDATION.** *Bothrops pictus* is endemic to Peru where it occurs mainly along the western slope of the Andes and in coastal deserts (Campbell and Lamar 2004. The Venomous Reptiles of the Western Hemisphere, Vol. 1. Cornell Univ. Press, Ithaca, New York. 475 pp.). *Pseudalsophis elegans* occurs in dry habitats along the Pacific coast from southern Ecuador to Chile (Myers and Hoogmoed 1974. Zoologische Mededelingen 48:187–194). Information on the ecology of both species is scarce. We herein report predation on these species by a large bird of prey, *Geranoaetus melanoleucus* (Black-chested Buzzard-Eagle).

On 18 September 2011, at 1127 h, in the Reserva Nacional Lomas de Lachay, Lima, Peru (11.3533°S, 77.3686°W; datum WGS84), we observed a *G. melanoleucus* perched in a Tara Tree (*Caesalpina spinosa*) feeding on a *Pseudalsophis elegans* (Fig. 1a). After it had finished feeding, the bird took flight and started circling low over the vegetation. After only about 4 min it descended to the ground and caught a *Bothrops pictus* in the dense herbaceous vegetation. The eagle carried the viper to another tree and immediately started to feed on it (Fig. 1b). *Geranoaetus melanoleucus* preys primarily on mammals, with its diet containing only a minor percentage of reptiles (Paves et al. 1992. J. Raptor Res. 26:27–32; Trejo et al. 2006. Hornero 21:31–36). Because of its high abundance at Lomas de Lachay, *G. melanoleucus* might nevertheless be an important predator of snakes in this region.

DMD acknowledges support from the research funding program "LOEWE – Landes-Offensive zur Entwicklung wissenschaftlich-ökonomischer Exzellenz" of Hesse's Ministry of Higher Education, Research, and the Arts.

***CLELIA LANGERI*. DIET**. The pseudoboine snake, *Clelia langeri*, is a Bolivian endemic and inhabits the inter-Andean dry valleys of the Santa Cruz and Chuquisaca Departments, and possibly the dry valleys of Tarija Department (Reichle and Embert 2005. J. Herpetol. 39:379–383). Data on the diet of the species are lacking, as the only known prey item is a mouse (Muridae) found in one of the specimens from the original description (Reichle and Embert, *op. cit.*). Here we report a new prey item and the first occurrence of a snake in the diet of *C. langeri*.

On 8 February 2011, at 0730 h, we found a dead juvenile female *C. langeri* (SVL = 405 mm; tail length = 95 mm) that had been struck by a vehicle on the old Cochabamba highway (18.09°S, 64.14°W, datum WGS 84; elev. 1320 m), between the districts of Pampagrande and Mataral, Florida Province, Santa Cruz Department, Bolivia. When we inspected the *C. langeri*, we observed a snake protruding from the side of its body. Dissection confirmed that the prey item was a juvenile male *Philodryas psammophidea* (Chaco Racer; SVL = 255 mm, tail length = 105 mm) that had been consumed head-first. This observation not only provides the second known prey item for the species, but is also the first record of a snake in the diet of *C. langeri*. While anurans and small mammals are known prey items of *Clelia* species (Yanosky et al. 1996. Herpetol. Nat. Hist. 4:97–110), this report is consistent with previous observations of these species being ophiophagus predators (Delia 2002. Herpetol. Notes. 2:21–22, and references therein).

Funding for this research was provided by the Senckenberg Natural History Museum in Frankfurt, Germany. CMS was supported by a National Science Foundation's Graduate Research Fellowship and the Applied Biodiversity Science NSF-IGERT Program at Texas A&M University (NSF-IGERT Award # 0654377).

***COLUBER CONSTRICTOR* (North American Racer). COMMUNAL OVERWINTERING.** At ca. 1500 h on 6 April 2008, we observed a snake hibernaculum at Swan Lake National Wildlife Refuge, Chariton Co., Missouri, USA (39.624962°N, 93.225670°W, datum WGS84; air temp. ca. 16°C) on the west embankment of a pond. The entrance of the den was a hole approximately 3 cm in diameter and four *Coluber constrictor* were attempting to emerge from the hole simultaneously, thus inhibiting other individuals from doing so. The lower jaw of one *C. constrictor* appeared severely dislocated or damaged, perhaps by the pressure of the three other individuals attempting to emerge, and at initial observation the snakes seemed dead. Further investigation revealed that the snakes were, in fact, alive. We were able to reach inside the den and capture 12 additional *C. constrictor* (more individuals were observed but we could not reach them for capture) and individuals of four other species: *Pantherophis obsoletus* (N = 4), *Nerodia erythrogaster* (N = 1), *N. sipedon* (N = 1), and *Lampropeltis calligaster* (N = 1). We believe this is the first reported instance of a "three stooges effect" in snake den emergence, whereby several individuals attempt to exit a hibernaculum and inhibit not only their own emergence, but also that of the other individuals. The "three stooges effect" poses several potential negative effects, including cranial damage that inhibits feeding, increased conspicuousness to predators, or ultimately direct mortality from injuries caused by this behavior.

***CROTALUS ADAMANTEUS* (Eastern Diamondback Rattlesnake). REPRODUCTION / FEBRUARY AND MARCH BREEDING.** The majority of North American rattlesnakes have a single, annual mating season extending from late summer through early autumn (Aldridge and Duvall 2002. Herpetol. Monogr. 16:1–25). Courtship and mating of *Crotalus adamanteus* occurs in August and September throughout the geographic range, except in extreme southern Florida where *C. adamanteus* may also breed in December and January (Timmerman and Martin 2003. Conservation Guide to the Eastern Diamondback Rattlesnake, *Crotalus adamanteus*. SSAR Herpetol. Circ. 22). Here we provide observations of *C. adamanteus* engaged in breeding behavior outside of August and September in the northern half of the geographic range.

At 1440 h on 23 February 2012 (mostly cloudy, 27°C), JGP observed a copulating pair of adult *C. adamanteus* in Camden Co.,

Georgia, USA, in a heavily-thinned, open-canopied *Pinus taeda* plantation. When first encountered, the snakes were moving towards a branch pile, the female pulling the adjoined male. The snakes settled beneath the pile and had separated when JGP returned at 1528 h. At 1045 h on 3 March 2012 (overcast, 21°C), ZSB, MNM, and APD observed a copulating pair of *C. adamanteus* on Little Tybee Island, Chatham Co., Georgia, near the edge of coastal marsh. As the observers approached, the male detached from the female and crawled 3 m, hemipenes everted, into a hollow trunk of a fallen *Sabal palmetto*. On 18 March 2007, JLW, SHB, WGK, and JNH, observed a copulating pair of *C. adamanteus* on a private quail plantation in Colleton Co., South Carolina, in a mature, open-canopied, mixed-species (*Pinus elliottii, P. palustris, P. taeda*) savanna. Another adult *C. adamanteus* (sex unknown) was observed beneath the copulating pair. The breeding male was equipped with a radio transmitter and was previously observed copulating on 17 August 2006.

Our observations of copulatory behavior in *C. adamanteus* in February and March are at odds with previous observations of *C. adamanteus* mating behavior (Timmerman and Martin 2003, *op. cit.)* and with the peak in male plasma testosterone in July–September (which correlates with breeding; Hoss et al. 2011 Southeast. Nat. 10:95–108) in the northern portion of the geographic range. Our observations suggest the possibility of an extended breeding season (August–March) or a second, late winter–early spring breeding season in *C. adamanteus* in the northern portion of the range.

***CROTALUS AQUILUS* (Queretaran Dusky Rattlesnake). DIET.** Although *Crotalus aquilus* is known to feed on frogs, salamanders, small rodents, invertebrates, and lizards of the genera *Sceloporus* and *Gerrhonotus* (Klauber 1972. Rattlesnakes: Their Habits, Life Histories, and Influence on Mankind. University of California Press, Berkeley. x + 1533 pp.), details on which species of lizards are consumed have not been provided. Here we report two neonate male *C. aquilus* feeding on *Sceloporus grammicus* in the municipality of Epazoyucan, Hidalgo, Mexico, 2234 m elev. Both snakes were collected on 28 August 2011. The first snake (SVL = 190 mm; tail length = 20 mm; 8 g) contained an adult *S. grammicus* (SVL = 52 mm; tail length = 55) that had been swallowed head-first. The second snake (SVL = 245 mm; tail length = 30 mm; 11 g) contained an adult *S. grammicus* (SVL = 64 mm; tail length = 68 mm) that had also been swallowed head-first. Predator-prey mass ratios were approximately 1.3:1. The lizards were deposited in the hepetological collection of the Centro de Investigaciones Biológicas, Universidad Autónoma del Estado de Hidalgo (CH-CIB 4288, 4289).

LEONARDO FERNÁNDEZ-BADILLO (e-mail: cyrtopsis@hotmail.com), **NALLELY MORALES-CAPELLÁN** (e-mail: nahomi_naica25@hotmail.com), and **IRENE GOYENECHEA** (e-mail: ireneg28@gmail.com), Centro de Investigaciones Biológicas (CIB), Universidad Autónoma del Estado de Hidalgo, A.P. 1-69 Plaza Juárez, Pachuca, Hidalgo, México.

***CROTALUS LEPIDUS* (Rock Rattlesnake). DIET.** Several reports of *Crotalus lepidus* consuming other snakes exist in the literature (Beaupre 1995. Herpetologica 51:45–56; Mata-Silva et al. 2010. Herpetol. Rev. 41:235–236; Milstead et al. 1950. Texas J. Sci. 2:543–562; Williamson 1971. Herpetol. Rev. 3:18). On 16 August 2008, a male *C. lepidus* (SVL = 590 mm; tail length = 60 mm; 160 g) was found basking outside a burrow on Mesa Montoro, Sierra Fría, Municipality of San José de Gracia, Aguascalientes, Mexico (22.003794°N, 102.570860°W, datum WGS84; elev. 2374 m). Following capture, the snake regurgitated a small female *Lampropeltis mexicana* (Greer's Kingsnake; SVL = 520 mm; tail length = 100 mm; 45.49 g) that had been swallowed head-first. This is the first record of *L. mexicana* in the diet of *C. lepidus*. The rattlesnake was released, but the kingsnake was deposited in the Herpetological Collection, Universidad Autónoma de Aguascalientes (UAA-CV-0322). We later dissected the kingsnake's stomach and discovered a partially digested male *Sceloporus torquatus* (UAA-CV-0324; SVL = 80 mm; 18.84 g).

An additional male *C. lepidus* (SVL = 510 mm; tail length = 52 mm; 120 g) captured at the same locality on 2 August 2008, defecated body scales belonging to a *Phrynosoma orbiculare* (Mountain Horned Lizard; UAA-CV-0325), the only horned lizard known to occur in the area. This is the first record of *C. lepidus* consuming *P. orbiculare*, although the species is known to prey on other *Phrynosoma* species in other parts of its range (Dickerman and Painter. 2001. Herpetol. Rev. 32:46; Milstead et al. 1950, *op. cit.*).

We thank Jerry D. Johnson for comments on a previous draft of this note.

***CROTALUS OREGANUS CONCOLOR* (Midget Faded Rattlesnake). NURSERY AGGREGATION.** Over the past two decades, our perception of rattlesnake sociability has gone from completely asocial to remarkably social. Aside from intra- and intersexual interactions during the breeding season, the only other obvious social behavior is aggregation that was historically viewed as coincidental or due to a common attraction to limited habitat features for activities like hibernation, ecdysis, and during the stages of pre- and post-parturition. However, aggregation can provide defensive or thermoregulatory advantages during vulnerable activities (Greene et al. 2002. *In* Schuett [ed.] Biology of the Vipers, pp. 179–206. Eagle Mountain Publishing, Eagle Mountain, Utah; Reiserer et. al. 2008. J. Zool. 274:277–283). During gestation, most rattlesnakes are particularly vulnerable to predators due to their more sedentary behavior and it is not surprising that many species form aggregations during this time. For the same reasons, it seems neonates of virtually all species of rattlesnakes remain together and with their mother during the time it takes for them to complete their first ecdysis. Yet the relationship between mothers and neonates seems to extend

beyond these relatively passive advantages. Melissa Amarello (unpubl. data) documented more active tending of offspring in a post-parturition neonatal aggregation which more clearly demonstrates an active maternal behavior that goes beyond the general increase in defensiveness. To further elucidate these social interactions, we investigated the relatedness of female *C. o. concolor* and their associated litters based on 16 microsatellite loci (Holycross et al. 2002. Mol. Ecol. Notes 2:537–539; Oyler-McCance et al. 2005. Mol. Ecol. Notes 5:452–453; Oyler-McCance and Parker. 2010. Conserv. Genet. Res. 2:123-125; Villareal et al. 1996. J. Hered. 87:152–155). We estimated relatedness using the triadic likelihood estimator (Wang 2007. Genet. Res. 89:135–153) implemented in the software CoAncestry (Wang 2011. Mol. Ecol Res. 11:141–145).

We discovered two gravid female *C. o. concolor* at one of many known rookery sites in Sweetwater Co., Wyoming (Parker and Anderson 2007. J. Herpetol. 41:41–51). We visited the site daily until we found two clutches of offspring being attended by the two previously identified females. Although we had assumed that the groups of neonates were born to the females with which they were found, genetic analysis revealed that one female was attending a group of five offspring that were not related to her (average relatedness = 0.01; presumably she had not yet dropped her own clutch) and the other female was attending three offspring that were likely her own (average relatedness = 0.48; all confidence intervals overlapped 0.5) and one that was unrelated (relatedness = 0). Rather than a core family behavior to protect a female's own offspring, it appears that this social behavior is more like that of a nursery. Gravid *C. o. concolor* do not travel far from their hibernaculum and so all known rookery sites are in close proximity to hibernacula (Parker and Anderson 2007, *op. cit.*). While we have not yet looked at the relatedness within hibernacula, it is assumed that there is a higher degree of relatedness within hibernacula than between (Bushar et. al. 1998. Copeia 1998:411–422; Clark et. al. 2008. Mol. Ecol. 17:719–730). Thus, nursery aggregations appear to be a species level adaptation rather than kin selection.

JOSHUA M. PARKER, Clayton State University, Department of Natural Sciences, 2000 Clayton State Blvd., Morrow, Georgia 30260, USA (e-mail: midgetfaded@hotmail.com); **STEPHEN F. SPEAR,** The Orianne Society, 579 Highway 441 S, Clayton, Georgia 30525, USA; **SARA OYLER-MCCANCE,** USGS Fort Collins Science Center, 2150 Centre Ave., Building C, Fort Collins, Colorado 80526, USA.

***DEMANSIA VESTIGIATA* (Lesser Black Whipsnake). DIET.** The diet of *Demansia vestigiata* is primarily composed of ectotherms, ~75% of which are lizards (Shine 1980. J. Herpetol. 14:381–389). Frogs of the families Hylidae and Myobatrachidae have been recorded as prey items for *D. vestigiata* (Fearn and Trembath 2009. Aust. J. Zool. 57:49–54) but few (*Litoria rothii*, *L. verreauxii*, *Adelotus brevis*, and *Opisthodon ornatus*) have been identified to species level (Shine, *op. cit.*; Trembath and Rowley 2005. Herpetofauna 35:114–115.). A road-killed male *Demansia* sp. (total length = 91.5 cm) was collected at 1730 h on 22 Apr 2011 on Anzac Parade, in the tropics of the Northern Territory, Australia (12.58°S, 131.32°E, datum: WGS84). The snake had 180 ventral scale rows (Dowling 1951. Copeia 1951:131–134) and was identified as *D. vestigiata* (the morphologically similar *Demansia papuensis* has >198 ventral scale rows: Shea 1998. The Beagle 14:41–61). The snake's digestive tract contained four undigested Rocket Frogs (*Litoria nasuta*; Fig. 1; SVLs = 27, 27.5, 38.4, and 40 mm) and two unidentifiable partially digested frogs. Because

FIG. 1. *Demansia vestigiata* with three *Litoria nasuta* pictured in the orientation that they were ingested. Centimeter rule.

Demansia spp. are primarily diurnal and terrestrial, it is probable that they consume frogs sleeping at ground level (e.g., in soil cracks) during the day.

CRYSTAL KELEHEAR, School of Biological Sciences, A08, University of Sydney, Camperdown, New South Wales, 2006, Australia; e-mail: crystal.kelehear@hotmail.com.

***DRYMARCHON MELANURUS* (Central American Indigo Snake). DIET.** *Drymarchon melanurus* is known to feed on anurans, lizards, and snakes, including those of the genus *Bothrops* (Pérez-Higareda et al. 2007. Serpientes de la Región de los Tuxtlas, Veracruz, México. UNAM. Distrito Federal, México. 189 pp.). On 23 January 2008 we captured a male *D. melanurus* (SVL = 1670 mm; tail length = 310 mm) in riparian vegetation in the municipality of Tlaquiltenango, Morelos, México (18.458188°N, 99.04315°W; datum WGS84). During handling, the snake regurgitated a young male *Crotalus simus* (Middle American Rattlesnake; SVL = 640 mm; tail length = 14 mm). Although Solorzano (2004. Snakes of Costa Rica. Instituto Nacional de Biodiversidad, Costa Rica. 791 pp.) listed a second-hand report of a *D. melanurus* consuming a *C. durissus* (= *C. simus*), to our knowledge, this is the first detailed account of *C. simus* in the diet of *D. melanurus*. The *D. melanurus* was released at the capture location; the prey was deposited in the Colección de Anfíbios y Reptiles de la Universidad de Morelos (CARUM).

EDGAR E. NERI CASTRO, CARLOS A. MONTALBÁN HUIDOBRO, and **SAMUEL ARÉCHAGA OCAMPO** (e-mail: samuel.arechaga@uaem.mx), Facultad de Ciencias Biológicas, Universidad Autónoma del estado de Morelos, Av. Universidad 1001, Chamilpa 62209, Cuernavaca, Morelos, México.

***HETERODON SIMUS* (Southern Hog-nosed Snake). PREDATION.** *Heterodon simus* is a relatively poorly known species (Tuberville et al. 2000. J. Elisha Mitchell Sci. Soc. 116:19–40) with few documented predators. A *Drymarchon couperi* (Eastern Indigo Snake) that disgorged an *H. simus* (Mount 1975. The Reptiles and Amphibians of Alabama. Agriculture Experiment Station, Auburn Univ., Auburn, Alabama. 345 pp.), and a *Lampropeltis getula* (Common Kingsnake) that had eaten three *H. simus* (Palmer and Braswell 1995. Reptiles of North Carolina. Univ. North Carolina Press, Chapel Hill. xiii + 412 pp.), appear to be the only published records of predation on this species. Here I report additional instances of natural predation on *H. simus* on Sandhills Game Lands, ca. 16.4 km NNE of Old Hundred, Scotland Co., North Carolina, USA.

At 1440 h on 18 July 2009, in open sandhills dominated by Longleaf Pine (*Pinus palustris*), Turkey Oak (*Quercus laevis*), and Wiregrass (*Aristida stricta*), I encountered a large adult *Coluber constrictor* (Eastern Racer) swallowing a juvenile male *H. simus* (SVL = 220 mm; total length = 270 mm). At my approach, the racer quickly disgorged its dead and partially-swallowed prey and fled. The *H. simus* was deposited in the collection of the North Carolina State Museum of Natural Sciences (NCSM 75976). On 16 May 2009, at ca. 1130 h, a *Buteo lineatus* (Red-shouldered Hawk) was encountered preying on a telemetered adult male *H. simus* (NCSM 75915; SVL = 338 mm; total length = 430 mm). The hawk, which fled when approached, had deposited the snake (fatally injured but still moving) on a large Turkey Oak limb ca. 8 m above the ground. On 23 May 2009, the transmitter from a telemetered adult male *H. simus* was found, accompanied by a single breast feather from a young *Bubo virginianus* (Great Horned Owl), providing probable, though circumstantial, evidence of predation. On 7 August 2009, at 1920 h, a large telemetered adult female *H. simus* (NCSM 75996) was found beneath a tree, freshly killed with the anterior half consumed. A *Buteo jamaicensis* (Red-tailed Hawk) was heard vocalizing and observed moving away from the area as I approached, again providing strong, though inconclusive, evidence of the predator's identity.

Between 18 January 1999 and 10 May 2008, nine additional telemetered adult *H. simus* were taken by undetermined predators on Sandhills Game Lands and private lands in Scotland Co., North Carolina. In three instances, only the transmitter was found. Of the remaining six, at least portions of the carcass were found. In at least three of these cases, pieces of the vertebral column were found along with the transmitter beneath trees, stripped of flesh in typical raptor fashion. It is likely that most, if not all, of these snakes were taken by raptors or other predatory birds. In at least four cases, predation occurred soon after prescribed warm-season fires, which probably rendered snakes on the surface much more visible and accessible to raptors. These observations suggest that raptors are important predators of *H. simus*.

Fieldwork was made possible by Project Simus, which is supported by the North Carolina Herpetological Society, Wake Audubon, Three Lakes Nature Center, and the North Carolina State Museum of Natural Sciences. D. S. Dombrowski, L. S. Christian, G. A. Lewbart, J. B. Sealy III, M. E. Dorcas, and students at the North Carolina State University College of Veterinary Medicine assisted with transmitter surgeries. For field assistance, I especially thank T. J. Thorp, L. T. Pusser, T. A. Arnold, L. P. Gilleran, and M. C. Monroe. J. A. Gerwin confirmed the owl feather identification. The North Carolina Wildlife Resources Commission provided permits.

***LEPTODEIRA MACULATA* (Southwestern Cat-eyed Snake). DIET.** *Leptodeira maculata* was considered a full species by Duellman (1958. Bull. Amer. Mus. Nat. Hist. 114:1–152). Duellman (*op. cit.*) also recognized *L. annulata cussiliris* as a distinct subspecies but recent studies have synonymized Mexican populations of *L. a. cussiliris* with *L. maculata* (Daza et al. 2009. Mol. Phylogenet. Evol. 53:653–667; Mulcahy 2007. Biol. J. Linn. Soc. 92:483–500). The diet of *L. maculata* has been reported to include anurans, such as *Rhinella marina, Incilius mazatlanensis, I. valliceps, Dendrosophus robertmertensi, Scinax staufferi, Smilisca baudinii, Tlalocohyla smithii, Leptodactylus melanonotus, Hypopachus variolosus,* and an undetermined species within the *Lithobates* (*Rana*) *pipiens* complex, and lizards, such as *Norops* (*Anolis*) sp., *Aspidoscelis sacki, Hemidactylus frenatus, and Phyllodactylus lanei* (Duellman, *op. cit.*; Hardy and McDiarmid 1969. Univ. Kansas Publ. Mus. Nat. Hist. 18:39–252; Ramírez-Bautista 1994. Instit. Biol. Cuader. 23:1–127). Herein, we report the first record of *L. maculata* feeding on *Leptodactylus fragilis* (White-lipped Frog) in northern Oaxaca, México.

PHOTO BY R. MATA-SILVA AND A. MATA-RAIGOZA

FIG. 1. Juvenile *Leptodeira maculata* beginning to ingest an adult *Leptodactylus fragilis* on the outskirts of Papaloapan, Oaxaca, México.

On 29 April 2011, at 2020 h, a juvenile *L. maculata* was observed feeding on a live adult *L. fragilis*, during a rainy evening in the backyard of a home located on the outskirts of Papaloapan, Municipality of Tuxtepec, Oaxaca, Mexico (18.157883°N, 96.091658°W; datum: WGS 84; elev. 25 m). When the snake was first discovered, it was swallowing the hind legs of the frog (Fig. 1). After about five minutes, the snake had consumed the entire frog and retreated into nearby vegetation.

We thank L. D. Wilson and L. W. Porras for important comments on this note.

VICENTE MATA-SILVA, (e-mail: vmata@utep.edu) and **JERRY D. JOHNSON** (e-mail: jjohnson@utep.edu), Department of Biological Sciences, The University of Texas at El Paso, El Paso, Texas 79968, USA; **AURELIO RAMÍREZ-BAUTISTA,** Centro de Investigaciones Biológicas, Universidad Autónoma del Estado de Hidalgo, A.P. 1-69 Plaza Juárez, Pachuca, Hidalgo, C.P. 42001, México (e-mail: ramibautistaa@gmail.com).

***MASTIGODRYAS MELANOLOMUS ALTERNATUS* (Neotropical Racer). ELEVATION.** The sole representative of the genus *Mastigodryas* in Costa Rica, *M. melanolomus* is distributed from Mexico to Panama (Solorzano 2004. Snakes of Costa Rica. Editorial INBio, Santo Domingo, Costa Rica. 791 pp.). The elevational range is from sea level to 1760 m (Savage 2002. The Amphibians and Reptiles of Costa: A Herpetofauna Between Two Continents, Between Two Seas. Univ. Chicago Press, Chicago, Illinois. 934 pp.). Specimens in the Museo de Zoología at the Universidad de Costa Rica (UCR) confirm their presence up to 1500 m (Federico Bolaños, pers. comm.). On 25 December 2006 we found a dead *M. m. alternatus* (UCR 21210) at an elevation of 2137 m approximately 1 km from the start of the Sendero Catarata (Waterfall Trail) located in the community of San Gerardo de Dota, San Jose, Costa Rica (9.538°N, 83.818°W; datum WGS1984). Our observation is 377 m higher than any previous record of this species and may represent an up-slope range extension, similar to elevational shifts observed in Malagasy herpetofauna as a consequence of climate change (Raxworthy et al. 2008. Global Change Biol. 14:1703–1720.

***OPHEODRYS VERNALIS* (Smooth Greensnake). REPRODUCTION / COMMUNAL NESTING.** *Opheodrys vernalis* is an oviparous species with reported incubation times ranging from four days (Blanchard 1933. Pap. Michigan Acad. Sci. Arts Lett. 27:493–508.) to 30 days (Messmer et al. 1995. North Dakota State Univ. Extension Service, Fargo. 2 pp.). Several instances of communal nesting have been reported (Cook 1964. Herpetologica 20:206; Fowler 1966. Herpetologica 22:231; Gregory 1975. Copeia 1975:185–186; Lawson 1983. Herpetol. Rev. 14:20; Stille 1954. Nat. Hist. Misc. 127:1–111), with nests containing up to 30 eggs (Arbuckle 1999. *In* Hunter et al. [eds.], Maine Amphibians and Reptiles, pp. 171–173. Univ. Maine Press, Orono). Here we describe the largest communal nest of *O. vernalis* eggs to date.

On 30 June 2010, a communal nest of 85 *O. vernalis* eggs was found in Lake Co., Illinois, USA near the Illinois-Wisconsin border. The nest was found beneath the bottom layer of a two-layer plywood sheet located in an old field lot slated for development. The eggs were found in three large cohesive clusters with one egg deposited separately. The clusters contained 14, 24, and 47 eggs; eggshells from past years were present beneath the plywood. Because of the imminent site development, the eggs were collected for incubation for a local *O. vernalis* recovery program with the Lake County Forest Preserve District and Lincoln Park Zoo. Eighty-three of the 85 eggs successfully hatched; one egg had desiccated prior to incubation and the lone egg that was separate from the clusters did not hatch. The incubation period ranged from 22 to 26 days (22–28 July). There were five synchronous bouts of hatching with 12 to 27 hatchlings per day. Mean SVL and mass of neonates was 102 ± 6.46 mm (range = 90–114 mm) and 1.17 ± 0.14 g (range = 0.97–2.0 g), respectively.

Clark Street, Chicago, Illinois 60614, USA (e-mail: asacerdote@lpzoo.org); **GARY GLOWACKI**, Lake County Forest Preserve District, Grayslake, Illinois 60003, USA (e-mail: gglowacki@LCFPD.org); **TODD SCHMITZ**, Waukegan, Illinois 60087, USA.

***OXYBELIS WILSONI* (Yellow Snake). REPRODUCTION.** *Oxybelis wilsoni* is a large colubrid (to ca. 1982 mm total length; McCranie 2011. The Snakes of Honduras. Systematics, Distribution, and Conservation. SSAR. Ithaca, New York. x + 714 pp.) that is endemic to Isla de Roatán, Islas de la Bahía, Honduras. Groves (1995. Rev. Biol. Trop. 43:307–309) reported that a wild caught captive female laid eight eggs on 7 September (corresponding to the early rainy season on Roatán), two of which hatched 92 and 94 days later. Nothing else has been reported on reproduction of this species.

On 21 May 2011, we collected a gravid female *O. wilsoni* (MVZ 267201: total length = 1758 mm) 1 km E of Pollytilly Bight, Roatán, Honduras (16.406300°N, 86.388083°W, datum WGS84; elev. 25 m). Dissection of the snake revealed that it contained four large oviductal eggs (MVZ 267201) in an early stage of development, thus suggesting a deposition of the eggs during the early portion of the rainy season (July–January, with peak during October and November; McCranie et al. 2005. The Amphibians & Reptiles of the Bay Islands and Cayos Cochinos, Honduras. Bibliomania!, Salt Lake City, Utah. xiv + 210 pp.).

***PHILODRYAS PATAGONIENSIS*. DEFENSIVE BEHAVIOR / THANATOSIS.** *Philodryas patagoniensis* is a medium-sized terrestrial snake that occurs in Brazil, Bolívia, Paraguay, Argentina, and Uruguay (Peters and Orejas-Miranda 1970. Catalogue of the Neotropical Squamata. Part 1, Snakes. Nat. Mus. Bull., Washington D.C. 347 pp.). This species feeds on a wide range of prey including anurans, fishes, lizards, birds, and snakes (Pontes et al. 2003. Herpetol. Rev. 34:154). Here we present the first case of thanatosis (death-feigning) in *P. patagoniensis*. At 1000 h on 3 November 2007, during a survey at Balneário Pinhal, Rio Grande do Sul state, southern Brazil (30.2042°S; 50.8700°W, datum: Corrego Alegre), we captured an adult male *P. patagoniensis* (total length = 940 mm) that exhibited thanatosis during handling. The behavior continued even after the animal was released on the ground. Thanatosis is usually exhibited in response to external stimuli (Greene 1988. *In* Gans and Huey [eds.], Biology of the Reptilia, pp. 1–152. Alan R. Liss, Inc., New York) and immobility might discourage sequential attacks, allowing the prey to escape (Santos et al. 2010. Biota Neotrop. 10:4).

OLIVEIRA** (e-mail: rbolivei@pucrs.br), and **GLÁUCIA M. F. PONTES** (e-mail: glaucia.pontes@pucrs.br), Laboratório de Herpetologia, Museu de Ciências e Tecnologia da PUCRS, Porto Alegre, RS, Brazil.

***SONORA SEMIANNULATA* (Western Groundsnake). PREDATION.** Greater Roadrunners (*Geoccocyx californianus*) are notorious for including lizards and snakes in their diet, although less is known about what prey items are fed to their nestlings (Maxon 2005. The Real Roadrunner. Univ. Oklahoma Press, Norman. xiiiv + 124 pp.). Potential prey items available to nest-bound young include arthropods, amphibians, reptiles, birds, and mammals (e.g., 90% vertebrates: Maxon, *op cit.*; primarily lizards: Ohmart 1973. Condor 75:140–149). Meinzer (1993. The Roadrunner. Texas Tech Univ. Press, Lubbock. 112 pp.) suggested that prey fed to nestlings were usually obtained opportunistically in response to their seasonal abundance, even though he saw adults feeding only on highly abundant grasshoppers, while at the same time more nutritious vertebrates were almost exclusively fed to the nestlings.

Sonora semiannulata is a small burrowing snake occurring in the deserts and grasslands of the southwestern U.S. and northern México (Conant and Collins 1998. A Field Guide to Reptiles and Amphibians of Eastern and Central North America, 3rd ed. Houghton Mifflin, Boston, Massachusetts. xviii + 616 pp.). It is normally nocturnal, although surface activity has been reported during daylight in early spring when temperatures are cool, and occasionally after heavy summer rains (Werler and Dixon 2000. Texas Snakes: Identification, Distribution, and Natural History. Univ. Texas Press, Austin. xv + 437 pp.). Predation on *S. semiannulata* has occasionally been documented by invertebrates (e.g., *Scolopendra heros*; Johnson et al. 2007. Herpetol. Rev. 38:93–94) and vertebrates (Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Institution Press, Washington, D.C. 668 pp.). Herein we report the first account of a *G. californianus* transporting a *S. semiannulata* to its nest and subsequently feeding it to its nestlings.

FIG. 1. A) An adult *Geococcyx californianus* (Great Roadrunner) with a freshly killed adult *Sonora semiannulata*; B) one of the *G. californianus* nestlings (a) swallowing the *S. semiannulata* (b) on Indio Mountains Research Station, Hudspeth Co., Texas.

On 11 September 2010, at 1300 h, an adult male *G. californianus*, in association with a female, was observed near its nest in a Catclaw (*Acaccia greggii*) carrying a freshly killed adult *S. semiannulata* (Fig. 1A). The nest, which contained three chicks and an infertile egg, was positioned next to the old ranch house in the headquarters compound on Indio Mountains Research Station (IMRS); which is located in the northern Chihuahuan Desert, 40 km SW of Van Horn, Hudspeth Co., Texas, USA (30.776883°N, 105.016060°W, datum WGS84; elev. 1233 m). Initially the snake was given to one of the hungry nestlings, however, a second nestling started consuming the snake by the tail (Fig. 1B). Eventually the first nestling was able take the snake away from the other nestling and swallow it whole.

We thank A. Harris who kindly provided us with some of the literature sources. Field work at IMRS was partially funded by an NSF FSML RET supplement awarded to J. D. Johnson for supporting B. Barragan and D. Griffith.

VICENTE MATA-SILVA (e-mail: vmata@utep.edu), **JERRY D. JOHNSON, GENEVIEVE BARRAGAN, ARTURO ROCHA**, **WILLIAM D. LUKEFAHR**, and **ROSS O. COUVILLON**, Department of Biological Sciences, The University of Texas at El Paso, El Paso, Texas 79968, USA.

***TANTILLA IMPENSA*. REPRODUCTION.** *Tantilla impensa* is apparently the largest known species of *Tantilla* with adults reported to reach ca. 725 mm total length (Campbell 1998. Sci. Pap. Nat. Hist. Mus., Univ. Kansas 7:1–14). Almost nothing is known about the natural history of this species (summarized in McCranie 2011. The Snakes of Honduras. Systematics, Distribution, and Conservation. SSAR. Ithaca, New York. x + 714 pp.). On 22 April 2011, we collected a gravid female *T. impensa* (MVZ 267218; total length = 461 mm) under a log near the Quebrada Piedras Colorados on the northeastern slopes of Cerro Azul, Copán, Honduras (15.128583°N, 88.900250°W, datum WGS 84; elev. 1450 m). After sedating the snake prior to preservation, we removed two shelled oviductal eggs (MVZ 267218) that measured 25.9 x 6.1 mm and 26.0 x 6.3 mm, respectively (length x maximum diameter), three months after preservation in formalin. This is the first information on reproduction of *T. impensa*.

JAMES R. McCRANIE, 10770 SW 164th Street, Miami, Florida 33157–2933, USA (e-mail: jmccrani@bellsouth.net); **LEONARDO VALDÉS ORELLANA**, Gerente General de "Hondufauna," Investigador Privado, Colonia América, Bloque 9, Casa 1806, Comayagüela, MDC, Honduras (e-mail: leovalor@hotmail.com).

***THAMNODYNASTES SERTANEJO*. HABITAT.** *Thamnodynastes sertanejo* was described from two specimens from the states of Bahia and Pernambuco, in the semiarid region of northeastern Brazil (Bailey et al. 2005. Phyllomedusa 4:83–101). The geographic distribution of the species was expanded to northern Minas Gerais (Silveira and Cotta 2006. Herpetol. Rev. 37:364) and now includes the state of Ceará (Roberto et al. 2009. Herpetol. Rev. 40:239). All localities lie in the Caatinga domain between 250 m and 700 m elevation (Roberto et al., *op. cit.*; Silveira and Cotta, *op. cit.*). Here, I report finding *T. sertanejo* at ca. 900 m elevation on the Santa Gertrudes farm (14.645278°W, 40.442500°W; datum WGS84), municipality of Planalto (Coleção Zoológica Gregório Bondar - CZGB 2552), now the highest elevation where the species has been recorded. Moreover, I present the first records of *T. sertanejo* outside of the Caatinga domain in vegetation types transitional to wetter areas of the Atlantic rainforest. One specimen (CZGB 6873) was found in liana forest (mata-de-cipó) on the Engenho farm (14.385833°W, 40.196111°S; datum WGS84), municipality of Boa Nova. Two specimens were collected in mesophytic forest. One of them on the Santa Gertrudes farm, referred above (CZGB 2552), another in the municipality of Itagibá (Museu de Zoologia da Universidade Estadual de Santa Cruz - MZUESC 4528). A fourth specimen (CZGB 6404) was found at the Bonfim farm (14.716982°W, 39.610057°S; datum WGS84), municipality Almadina, in ombrophilous forest near of the contact zone between mesophytic forest and ombrophilous forest. The new easternmost record of the species (Almadina) is only 60 km from the coast. All new localities are situated in the state of Bahia, Brazil.

ANTÔNIO JORGE SUZART ARGÔLO, Universidade Estadual de Santa Cruz – UESC, Km 16 Rodovia Ilhéus-Itabuna, CEP 45662-900, Ilhéus, Bahia, Brazil (e-mail: ajargolo@gmail.com).

Field Guide to the Amphibians of the Eastern Arc Mountains and Coastal Forests of Tanzania and Kenya

by Elizabeth B. Harper, G. John Measey, David A. Patrick, Michele Menegon, and James R. Vonesh, with Kiswahili translation by Imani Swilla. 2010. Camerapix Publishers International, Nairobi (www.camerapixpublishers.com). Softback. 320 pp. 1500 Kenya Shillings (approximately US $15.00). ISBN 978-1-904-722-48-9.

STEPHEN SPAWLS
7 Crostwick Lane, Spixworth, Norwich NR10 3PE, England
e-mail: stevespawls@hotmail.com

Approach a rain-fed pool at night in Kenya's coastal forests and you will appreciate the impact of the amphibian fauna; the ear-splitting cacophony that booms through the night tells you of the presence of fifteen or more species of frog, all shouting to attract a female. But for most of the 20th century, natural historians in East Africa had little visual material to aid in the identification of amphibians. We had to rely on local experts who knew a lot but published little; Arne Schiøtz has described this reluctance to commit to paper as the "Nairobi Museum cramp." Some South African-based books were useful, like Passmore and Carruthers (1979). Schiøtz's (1975) paper illustrated some 80-odd species of treefrogs, largely with black and white photographs but with a handful of color pictures, and his 1999 book covered, with maps and color illustrations, all the then-recognized African hyperoliids and rhacophorids. Hedges (1983) book had (generally poor) color pictures of some 16 East African anurans. With the turn of the century, matters improved, Channing's comprehensive 2001 guide to the amphibians of Central and Southern Africa covered a good number of East African species. Finally, Channing and Howell's authoritative 2006 *Amphibians of East Africa* provided us with a first comprehensive listing of the 203 amphibian species then known from East Africa. But even then no illustrations were available for some 48 species, an indicator that much was still to be done. So a well-illustrated book with maps, which adds to our knowledge of the eastern African herpetofauna, is to be welcomed, particularly one by a team of authors with extensive pertinent field experience.

This book covers the amphibians of the East African coastal region, and includes the Eastern Arc mountains, the sandwich of land between that mountain chain and the Tanzanian coast, and the southern half of Kenya's coastal strip. It is a fascinating area, and lies within two biodiversity hotspots, the coastal forests of eastern Africa and the eastern Afromontane (Mittermeier et al. 2004). The Eastern Arc is a chain of ancient crystalline metamorphic mountains, formed over 500 million years ago as the two blocks of East and West Gondwana crunched together, twice. Stretching from the Udzungwas in southern Tanzania north to the Taita Hills in Kenya, the hills rise up to over 2000 m altitude and attract orographic rainfall, often over 1500 mm annually. The entire area, the mountains and the coastal strip, receives what is—for East Africa—a relatively large amount of rain, over 500 mm per year. As northeastern Africa has gradually dried out during the last 3000 years, the peaks have retained their forest, and hence act as refugia for a number of species of flora and fauna. The isolation of the peaks as the intervening forest has shrunk has created isolated gene pools with resulting speciation. The enclaves of high land are evolutionary "islands in the sky;" the area is full of endemics. And the usual problems apply; such areas in developing countries are under pressure for use for agriculture, exploitative forestry, and mining to serve the needs of a booming human population, to whom esoteric conservation is of little significance.

The text of this book is in English and Swahili and it is thus accessible to all who live in the area. The translation to Swahili was done by Professor Imani Swilla (her surname, appropriately, means spitting cobra!). The volume opens with 37 pages of useful essays on the area, habitat types, the historical perspective, conservation, and includes some habitat photographs. The bulk of the book, 278 pages, is given over to describing the 122 species of amphibians (113 frogs, nine caecilians) found in the area, 20 of which are endemic to the mountains themselves, and several of these have been described in the last 15 years. The book concludes with a reasonable five-page bibliography. There is no index or keys. In almost all cases, each taxon described has a double-page spread, the English on the left hand page, Swahili on the right, each accompanied by a color photograph and a distribution map. On the top of the right-hand page are a set of symbols that tell the reader at a glance various bits of information, for example whether the animal likes reeds or grassland, is arboreal or not, is only found at high altitude, etc. The combination of picture, map, and symbol means that even an illiterate rural dweller can get something out of this book. For each species scientific name (using fully up-to-date taxonomy), authors and date, and English name are given and there are further headings for SVL (snout–vent length), description, similar species, habitat, natural history, call, distribution, type locality, elevational range,

and conservation status. The Swahili description uses the same headings (translated, obviously) but omits the call. Curiously, Swahili names are given for the first 20 or so species in the book (the *Leptopelis* and the Brevicipitidae) but no others. I'm not sure if this is a mistake or whether the authors simply gave up, as the Swahili names as given have been coined for this volume. Thus, *Arthroleptis stenodactylus*, the Shovel-footed Squeaker, has been given the Swahili moniker "Chura filimbi mwenye mguu kama koleo," meaning literally "the flute frog possessing legs like a spade." It doesn't trip off the tongue and is not a name I can imagine any Usambara farmer using.

The color pictures, by a range of talented photographers (mainly the authors) are mostly of credit-card size (there are a few full page spreads) but are simply excellent, virtually all are pin-sharp, with good depth of field and show the animal on a natural background. These are the gems of Tanzanian herpetology. Beauty, variety, and stunning colors jump out at you; there are purple and custard-yellow frogs, orange and green, and deep black frogs, and the vividly red-eyed *Leptopelis parkeri*. The tragic Kihansi Spray Toad, *Nectophrynoides asperginis* is here, but is no longer extant in the wild. No illustrations were available for a few species, including some such as *Amietia tenuoplicata*, described (as *Rana tenuoplicata*) by the eccentric English frog hunter Martin Pickersgill in his own 2007 book, *Frog Search*; the designated types for several new forms described in Pickersgill's weird book include specimens in his personal collection!

The maps in the guide are also small, but adequate, although the shades used are initially confusing; the lowland is blank, the mountains are lightly stippled. If a species occurs in the mountains its range there is shown in black, if it occurs elsewhere its range is hatched in grey. The maps also cover a huge area north and west of the mountain chain but no distributions are shown there, even if the species is found in that area.

It is often said that the more regional a guide is, the more useful it is, and this fits the bill perfectly, a comprehensive guide to all the amphibians of a relatively small and yet extremely important area where much is to be discovered (I have in my possession a photograph of an unknown snake found in the Usambara Mountains that I cannot assign even to a genus, let alone a species). This book will heighten awareness about a crucial zone in conservation terms. It will be a boon to local naturalists, the more so since it was produced by a Kenyan publisher, Camerapix (founded by the famous Mohammed Amin, the award winning photographer who documented the Ethiopian famine of 1984 and was tragically killed in an Ethiopian Airlines hijack). The description and other useful information make it more than just a field guide, and the Swahili text renders it useful to the budding local enthusiasts. It is small (slightly less than duodecimo), tough, well bound, and easily slipped into a rucksack. There are a few typos, one I noticed is on page 20 where it says the National Museum of Kenya in Nairobi has 300,000 amphibians and reptile specimens (it should be 30,000). There is slight confusion on page 306, where a caecilian (*Boulengerula uluguruensis*) and a blind snake (*Letheobia uluguruensis*) are given the English names "darker pink" and "lighter pink," the editor has confused the names and the caption. The pictures could do with being larger (there is lots of white space). The absence of an index and any sort of listing means you have to hunt page by page if you're looking for a particular species. But these minor glitches are unimportant; this book is exactly what conservation in Africa calls for—a colorful, attractive, and yet sound guide, small and inexpensive and in a language that the majority of local people speak. The authors have done a service to the people of Tanzania. A follow-up is called for, covering the reptiles of this unique area.

JEFF BOUNDY
Louisiana Department of Wildlife and Fisheries
PO Box 98,000, Baton Rouge, Louisiana 70898-9000, USA
e-mail: jboundy@wlf.la.gov

In 2003 Whit Gibbons wrote that only 5% of surveyed biology majors at the University of Georgia—in a state with 53 species of caudate amphibians—had ever seen a live salamander; the percentage would certainly be much lower if one polled the general public. This disquieting reality inspired Gibbons and various coauthors to familiarize Southerners to the resident herpetofauna. The resulting series of books by Gibbons et al. have already covered snakes, lizards and crocodilians, turtles, and frogs and toads of the Southeast. In this concluding volume, Mitchell and Gibbons reiterate that few people are aware of the presence of salamanders, and write that their book is "meant to inspire an appreciation of salamanders." A quick flip through the pages of *Salamanders of the Southeast* reveals a wealth of information including images of the

spectacular range of colors and shapes of salamanders, insights into their mysterious world, and documentation of their distribution across the South.

Of the book Page 1 asks "Why salamanders?"—to which the authors reply: salamanders serve as environmentally sensitive links between terrestrial and aquatic systems, we are just beginning to understand their surprisingly complex social interactions, they constitute a very significant portion, both in diversity and biomass, of the ecosystems in which they live, and many are, to some degree, in danger of extirpation. Inspired to read further, I learned that the southeastern United States offers an excellent introduction to salamanders, being inhabited by one sixth of all known species, and seven of the ten extant families of Caudata. A "boot camp" introduction covers salamander diversity, energetics, feeding and defense, social behavior, reproduction, taxonomy, and a guide to characters useful in identifying species. The introduction concludes with a photographic essay of salamander habitats, with details of the sorts of species that inhabit each of them. In the battle between authors, trying to educate and disseminate science, and the publisher, doing its best to mass-market a product, everyone is a winner in this instance, as *Salamanders of the Southeast* is attractive, readable and educational. Like an elementary school textbook, it sports a number of highlighted "Did you know?" boxes in the margins. I only scored 83%, and now know that hellbenders, a.k.a. "snot otters," can drop one side of their jaw to vacuum prey into their mouths, female newts glue a leaf around each egg that they deposit, and male plethodontids vaccinate females during courtship to make the latter receptive.

Salamanders of the Southeast is very nicely produced; it is sturdy, with glossy pages in a stiff paper jacket. There are 463 color photographs of salamanders, most of exceptional quality, showing the variation within species as well as the larvae and eggs of some. There are pictures of salamanders eating and being eaten, fighting and courting, artfully posed against habitat backdrops, and having researchers conducting research upon them. The species accounts are segregated into obligate aquatic, stream and seep, seasonal wetland, and fully terrestrial taxa. An unfortunate result of the arrangement is that *Desmognathus marmoratus* and *D. wrighti* are widely separated in the text from their congeners. Each species account includes a shaded distribution map and a brief tabular summary of body form, color pattern and costal groove count. The text for each account provides a detailed synopsis of Description (adults, larvae and juveniles), Similar Species, Distribution, Habitat, Behavior and Activity, Food and Feeding, Reproduction, Predators and Defense, Conservation, and Taxonomy. The Similar Species section contains useful clues in distinguishing between closely related, sympatric taxa (e.g., *Desmognathus welteri* has dark toe tips), but often, though realistically, the key elements are subjective: "larger," "more," "darker," etc. Confirmation of the utility of the book as a field guide awaits my travel into regions with an abundance of "look-alike" species. Rare errors in the book should be inconsequential to the average reader (e.g., Grotto Salamander occurring in Texas; "artisan" springs should read "artesian"; no *Necturus* in Florida according to range map). Finally, just before a useful glossary and bibliography, the authors present a tabular list of the species that occur in each state.

The main text portion of the book concludes with a chapter titled "People and Salamanders." The first page asks "Why do herpetologists study salamanders?" I am often asked that question by the "what-good-are-they" crowd, and have never developed a satisfactory response. Mitchell and Gibbons, however, provide a commendable answer in this sub-chapter by explaining why salamanders are important research subjects, and by illustrating aspects of study such as setting minnow traps and looking under rocks (a picture of someone bundled in a coat or enshrouded in rain gear would have added some authenticity!). Next, "Keeping Salamanders as Pets" reads as though the authors were forced to address that topic. They begin their discussion with a neutral tone, but follow with a discouraging checklist of factors that must be addressed before anyone makes the grim mistake of removing an amphibian from the wild. In case the reader is oblivious to those hints, an adjacent marginal note provides a snippet about salamander extinctions. The last sub-chapter, "A Conservation Vision for Salamanders," contains some doom-and-gloom prospects for salamander survival, but there is a pleasant surprise—the authors provide solutions. Rather than touting pointless, protectionist "listings," the authors suggest a number of ways in which landowners can manage their properties from the perspective of salamander habitat, including resources to guide in restoration of degraded areas. With that concluding point, the authors have presented a perfect circle of argument within the book's covers: salamanders are in trouble—they are magnificent creatures of which you may know very little—here is a lot of information about them—and this is what you can do to help them out of trouble.

The authors make important points to the newly-inspired salamander watcher: "Salamanders will not show themselves to you" and "go out with a naturalist who knows how to find salamanders…." I recently had the opportunity to explore the salamander-rich Appalachians for the first time, along the Appalachian Trail straddling North Carolina and Tennessee. While attempting to prod a salamander out of a hole in a log, a young man with a burdening backpack stopped to ask what I was doing. At that moment the salamander leapt into my cupped hands and I announced that it was a Blue Ridge Dusky Salamander. Perceiving that I might be a salamander biologist (at the 83% level), the man began interrogating me about a salamander he had seen on his hike northward. Perhaps due to not having talked to anyone in days, or to being in no hurry to get to Maine, he followed me about as I zigzagged from log to log. He shared my excitement as I encountered species I had not previously seen in life: the satiny smoke-colored Gray-cheeked Salamanders, the brightly spackled Slimy Salamanders, and the two-handed, tomato-backed Yonahlossee Salamanders. My time was limited, and I left him searching the logs on his own. Whether coating one's hands with gluey secretions, or resplendently beaming from the printed page, salamanders present a mysterious fascination.

As its title indicates, this new opus provides an overview of the batrachofauna of Central Africa (Cameroon, Central African Republic, Gabon, Democratic Republic of Congo, Equatorial Guinea, Republic of Congo, and São Tomé and Príncipe) and Angola. It also offers an identification key to the amphibians of Gabon and Mbini (the continental part of Equatorial Guinea)—a most welcome and useful addition, since a key for these countries has not thus far been available.

The book is divided into six chapters (the first five exclusively in French), respectively presenting: a brief introduction to the geography of the area covered (pages 10–16), a list of the amphibian species of the area, with a synthetic table showing their occurrence in the countries treated (pp. 17–45), a zoogeographical analysis of the Central African batrachofauna (pp. 46–62), remarks on conservation aspects (pp. 63–64, 97–101), natural history notes on species from Gabon and Equatorial Guinea (pp. 102–109), and an identification key to amphibians of Gabon and Mbini, in French (pp. 111–166) and in English (pp. 168–205), abundantly illustrated by good black and white drawings. On pages 65–96, color plates show good photographs of main ecological habitats and of 60 species in life, some of them illustrated by several photographs. The book is printed on glossy, high-quality paper and is solidly bound. The bibliography includes 636 references. It is followed by a section classifying references by country, an extremely useful feature if ones wishes to build a good reference library on given countries.

The second chapter, on the distribution of amphibians, provides data at the species level, without details on the distribution of subspecies. The table listing species' distributions also lists synonyms. Frétey (pers. comm.) kindly drew our attention to a mistake in the synonymy provided for *Conraua goliath* (Boulenger, 1906) (Ranidae): *Rana* (*Conraua*) *niedeni* Parker, 1936 is not a synonym of the latter species, but of *C. robusta* Nieden, 1908. This chapter includes an interesting section on the rare species that should be searched for, mostly because they are still known only from their type series. Regarding *Leptodactylodon blanci* Ohler, 1999 (Arthroleptidae), Frétey et al. indicate that it is so far known only from its male holotype, but that Rödel indicated in a personal communication that more Gabonese specimens exist in the Berlin collections; these specimens are actually part of a series that one of us (OSGP) participated in collecting in Moukalaba-Doudou National Park (Burger et al. 2006).

The third chapter, on zoogeography, provides, among other useful features, a map showing the number of amphibian families, genera, and species per country, tables showing the levels of endemism per country, and a table providing details on the sites within the region for which the batrachofauna has been inventoried, including field effort for each. This section is missing references to several Gabonese sites that have been extensively inventoried, including Loango and Moukalaba-Doudou National Parks and the Rabi oilfields (Burger et al. 2006; Pauwels 2009).

The identification key includes all species (but does not treat subspecies) currently recorded from Gabon and Mbini, plus several species known from southern Cameroon and likely to be found in Gabon and Mbini. There is a short but useful introductory section explaining how to use the key. The key was designed for using only external diagnostic characters visible to the naked eye, making it possible to identify live animals in the hand. The key to all species is followed by a section specifically describing the external characters of the *Hyperolius* spp. found in Gabon and Mbini, as a help for these highly variable and difficult to identify frogs. In the English key on page 187, entry 73a, to *Hyperolius ocellatus* Günther, 1859 (Hyperoliidae) wrongly sends the user to Appendix F, as the species is actually dealt with in Appendix I. Entry 117b of the English key, to *Arthroleptis variabilis* Matschie, 1893 (Arthroleptidae) has an unfortunate mistyping: "atypical median clear line" should read "a typical median clear line." In several instances (entries to *Leptodactylodon* Andersson, 1903 on p. 197 and to *Hyperolius kuligae* Mertens, 1940 on p. 202) in the English key, the word "large" has been used while the authors actually meant "broad," due to a "false friend" translation from French. The English part of the book would have certainly benefitted from a language review by a native English speaker.

Some taxonomic changes are proposed by Frétey et al. in their book. They place *Leptopelis crystallinoron* Lötters, Rödel & Burger, 2005, an unusual tympanum-less species whose description was based on a single adult female, in the synonymy of *L. brevirostris* (Werner, 1898), with no other justifications than its external resemblance to *L. brevirostris* and the fact that Amiet informed them that he had already observed a *L. brevirostris* that was missing a tympanum on one side of the head, hence they compare *L. crystallinoron* to a "five-legged sheep." Lötters et al. (2005) had, however, also stressed and illustrated striking differences in vomerine teeth shape. Having collected *L. brevirostris* in Gabon, including at the type locality of *L. crystallinoron* we noticed that *L. crystallinoron* was more massive and had a stronger dorsal granulation than *L. brevirostris*, in agreement with observations made by Lötters et al. (2005). In addition, several

additional *L. crystallinoron* specimens have been collected at the type-locality (Bell et al. 2010; Bell, pers. comm., 2010). It consequently seems that this synonymization by Frétey et al. is unjustified and does not serve to improve the already complex taxonomy of western central African *Leptopelis* spp. Moreover the key will not be usable for identifying *Leptopelis crystallinoron*, as the entry for *L. brevirostris* does not make any mention of *L. crystallinoron* and does not mention the existence of individuals without a tympanum. Similarly, although Frétey et al. treated them as distinct species in their synoptic taxonomic list, they mentioned that *Werneria submontana* Rödel, Schmitz, Pauwels & Böhme, 2004 (Bufonidae) "would be a subspecies of *Werneria preussi* (Amiet, pers. comm.)," and that *Cardioglossa alsco* Herrmann, Herrmann, Schmitz & Böhme, 2005 (Arthroleptidae) is "in all likelihood a synonym of *Cardioglossa pulchra* (Amiet, pers. comm.)." In the species list, page 26, *Cardioglossa manengouba* Blackburn, 2008 is listed as a synonym of *C. oreas* Amiet, 1972, again mostly based on a personal communication by Amiet, as indicated in a short footnote. All these vague statements would have deserved some proper justifications, as such they are just adding taxonomic confusion.

The *Kassina* sp. (Hyperoliidae) from Gabon mentioned by Frétey et al. in the species list (p. 35) and the identification key (pp. 124 and 175) without any further detail actually corresponds to the undescribed *Kassina* sp. mentioned by Burger et al. (2004, 2006) and Pauwels and Rödel (2007) from the Monts Doudou, as confirmed by Frétey (pers. comm.).

As the authors indicate on p. 17, they took into account all available batrachological literature from 1834 to December 2008, with only a few references from early 2009. During the gap between end of 2008 and the publication of the book in 2011, due to a lengthy editing treatment by the publishing house, only one reference was cited because it described three species from the region treated (Barej et al. 2010), and the authors insisted on having it mentioned in an addendum (T. Frétey, pers comm.).

The map showing the protected areas in Central Africa (p. 98) does not show most of the national parks of Gabon; in 2002 a network of 13 national parks was created, which covers about 11% of the country's territory and houses 86% of the amphibian species known to occur in Gabon (Christy et al. 2008; Pauwels 2008; Pauwels and Rödel 2007).

The absence of commas in the authorships in the literature references renders some references very confusing, especially when there are multiple authors; this reference format, probably imposed by the publishing house, is certainly not to be encouraged.

The literature references list for São Tomé and Príncipe lists Haft and Franzen (1996), but this reference does not appear in the literature cited, so we list it below.

The taxonomical index provides an incomplete list of pages where taxon names appear in the work, for instance the listing of taxa in Table 2 (list of all species from Central Africa and Angola) is mostly not referred to in the index, the synonyms listed in the species list are not included, and the appearance of names in the English and the French keys is not at all referred to in the taxonomical index. The toponymic index unfortunately does not include the localities on the photos (the authors should by the way be congratulated for providing a locality for their photos, which too many authors still do not do). Mistypings are very few in the book, and are mostly concentrated in the English text.

We tried the key to identify ten Gabonese amphibian specimens; all could satisfactorily be identified except the two *Hyperolius* spp. we had. In spite of the appendix dedicated to this genus, we encourage the key users to double-check their identifications with other literature reference on the genus *Hyperolius*, and the same should be done with other difficult genera such as *Leptopelis* and *Ptychadena*.

The few criticisms above should not obscure the fact that this new book represents a major step in the study of the batrachofauna of Gabon and Mbini, since the best tools available so far were mostly descriptions and keys developed by Jean-Louis Amiet and Jean-Luc Perret in various papers, often outdated, for Cameroonian amphibians. This new identification tool will undoubtedly allow a faster development of local species inventories and a better understanding of the distribution and conservation status of the amphibians of Gabon and Mbini.

Acknowledgments.—We are grateful to Rayna C. Bell (Cornell University, Ithaca), Thierry Frétey (Médréac), and Mark-Oliver Rödel (Museum für Naturkunde, Berlin) for providing useful information.

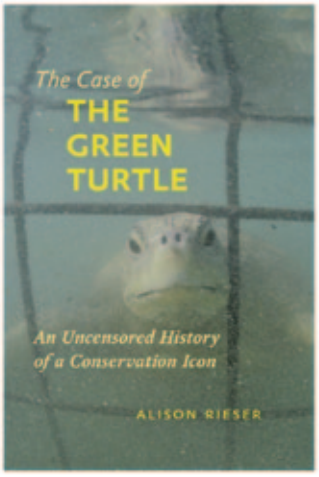
PUBLICATIONS RECEIVED

The Family Xenosauridae in Mexico / La Familia Xenosauridae en México

by Julio A. Lemos-Espinal, Geoffrey R. Smith, and Guillermo A. Woolrich-Piña. 2012. ECO Herpetological Publishing & Distribution, Rodeo, New Mexico. 106 pp. Softcover. US $16.95. ISBN 978-0-9832789-6-2.

The Xenosauridae is an enigmatic family of lizards consisting of a single genus, *Xenosaurus*, confined to Mexico and Guatemala. All species are live-bearing, with an unusually protracted gestation (up to nine months). These are mostly sedentary lizards, whose dorsoventrally flattened bodies reflect an intimate association with rock crevices. This book brings together a burgeoning scientific literature on xenosaurids, summarizing data on identification, morphology, coloration, distribution, habitat, behavior, diet, taxonomy, and etymology, all contained within individual species accounts. At present, there are six named species—all monotypic with the exception of *X. grandis*, with five subspecies. Information is presented for each species plus two undescribed forms from Hidalgo-Veracruz and Querétaro. The lizards and their habitats are illustrated with 81 color figures. A gazetteer presents specific distributional data for each species, including point-locality range maps and a list of known localities accompanied by geocoordinates. A comprehensive list of references is provided. A great deal of information is packed into this small book. The dual English/Spanish text will help make this volume accessible to a broad community of herpetologists and biologists.



Frogs of South Australia, 3rd ed.

by Michael J. Tyler and Steven J. Walker. 2011. Michael Tyler and Associates, Belair, South Australia. 100 pp. Softcover. AUS $25.00 (approx. US $30.00 with shipping; available from Michael Tyler & Associates, PO Box 334, Belair, South Australia 5052). ISBN 978-0-646-56849-2.

Much has changed in our knowledge of South Australia's frog fauna since Edgar Waite's first treatment in 1929, at which time only 10 species were known to occur there. The present work recognizes 27 native species plus the introduced Cane Toad (*Bufo marinus*), and follows the first two editions of this book authored by Michael Tyler in 1966 and 1977. Of the native species, two are undescribed, one each belonging to the genera *Litoria* and *Pseudophryne*. For each species of frog there is a point-locality distribution map in color, together with a large, high quality color photograph of an adult frog (tadpoles are not illustrated). Informational text covers the essentials: description, advertisement call, breeding biology, habitat, and distribution. This small (15 x 21 cm), lightweight book is easily carried into the field, where it will efficiently serve to identify any frogs encountered.

The Case of the Green Turtle
An Uncensored History of a Conservation Icon
Alison Rieser

"While I recommend this book for readers interested in sea turtle and herpetological history, it will also give readers with no knowledge outside of academia a glimpse into the world of policy and politics in the conservation of amphibians and reptiles."
—C. Kenneth Dodd, Jr., *Herpetological Review*

"The science, economics, and policies in this case are central to all conservation issues that the world faces today. The lessons learned from this story are applicable by all those interested in saving what little is left of our natural world. It is one of the most important books of its kind in the last 30 years."
—James R. Spotila, author of *Sea Turtles: A Complete Guide to Their Biology, Behavior, and Conservation*

INFORMATION FOR CONTRIBUTORS

Herpetological Review is a peer-reviewed quarterly that publishes, in English, articles and notes concerning the study of amphibians and reptiles, as well as book reviews, commentaries, regional and international herpetological society news, and letters from readers directed to the field of herpetology. Articles reporting the results of experimental research, descriptions of new taxa, or taxonomic revisions are not published in ***HR***, but should be submitted to the ***Journal of Herpetology*** (for information, please refer to: http://www.ssarherps.org/pages/JHinstr.php). To submit a manuscript to ***HR***, please consult the SSAR webpage at:

<http://www.ssarherps.org/pages/HRinfo.php>

REPRINTS AND PAGE PROOFS

Page proofs are sent electronically to authors of all articles, book reviews, and obituaries, but are not prepared for natural history, geographic distribution, or herpetoculture notes. Proofs are sent as pdf files approximately 2–4 weeks prior to publication. High resolution electronic (pdf) reprints of notes, articles, book reviews, and obituaries are provided at no charge to the primary/corresponding author as a benefit of SSAR membership. Reprint files will normally be sent prior to the issue mailing date from the printer. Authors who are not current SSAR members may purchase pdf reprints from the SSAR Publications Office.

ADVERTISING

Herpetological Review accepts commercial advertising. Rates and copy information are available from the SSAR web page (http://www.ssarherps.org/pages/HRinfo.php).

Herpetological Review (ISSN: 0018-084X) is published quarterly (March, June, September, and December) by the Society for the Study of Amphibians and Reptiles at Central Michigan University, Department of Biology, 217 Brooks Hall, Mt. Pleasant, MI 48859, USA. Periodicals postage paid at Mt. Pleasant, MI 48859 and at additional mailing offices.

All rights reserved. No part of this periodical may be reproduced without written permission of the Editor, except that authors and their agents are permitted to reproduce and distribute their own articles and notes.

POSTMASTER: Send address changes to Breck Bartholomew, SSAR Publications Secretary, P.O. Box 58517, Salt Lake City, UT 84158. **MISSING OR DAMAGED ISSUE?** Please notify Breck Bartholomew, SSAR Publications Secretary (e-mail: ssar@herplit.com) for a replacement.

SSAR PUBLICATIONS

SSAR publishes seven different series: *Journal of Herpetology, Herpetological Review, Facsimile Reprints in Herpetology, Contributions to Herpetology, Herpetological Circulars, Herpetological Conservation*, and the *Catalogue of American Amphibians and Reptiles* (see below for CAAR details). SSAR members receive prepublication discounts on all *Facsimiles* and *Circulars* and on volumes in the *Contributions* and *Herpetological Conservation* series. A complete pricelist of Society publications is available at: http://www.ssarbooks.com/.

CATALOGUE OF AMERICAN AMPHIBIANS AND REPTILES

The ***Catalogue*** consists of loose-leaf accounts of taxa prepared by specialists, including synonymy, definition, description, distribution map, and comprehensive list of literature for each taxon. Covers amphibians and reptiles of the entire Western Hemisphere. Available for purchase from the SSAR Bookstore (http://www.ssarbooks.com/). Use the prices below to order back issues.

COMPLETE SET: NUMBERS 1–880	check website below for current pricing
INDEX TO ACCOUNTS 1–400: Cross-referenced, 64 pages	$6
INDEX TO ACCOUNTS 401–600: Cross-referenced, 32 pages	$6
SYSTEMATIC TABS (Ten tabs to fit binder: "Class Amphibia," "Order Caudata," etc.)	$6
IMPRINTED POST BINDER (Note: one binder holds about 200 accounts)	$35
INCOMPLETE SET: NUMBERS 1–190	$75
191–410	$85
411–840	$320

To order: make checks payable to "SSAR" and mail to Breck Bartholomew, SSAR Publications Secretary, P.O. Box 58517, Salt Lake City, Utah 84158, USA (fax 801/453-0489). e-mail: ssar@herplit.com. Online orders at: http://www.ssarbooks.com/.

SOCIETY FOR THE STUDY OF AMPHIBIANS AND REPTILES

www.ssarherps.org

The Society for the Study of Amphibians and Reptiles, the largest international herpetological society, is a not-for-profit organization established to advance research, conservation, and education concerning amphibians and reptiles. Founded in 1958, SSAR is widely recognized today as having the most diverse society-sponsored program of services and publications for herpetologists. Membership is open to anyone with an interest in herpetology—professionals and serious amateurs alike—who wish to join with us to advance the goals of the Society.

All members of the SSAR are entitled to vote by mail ballot for Society officers, which allows overseas members to participate in determining the Society's activities; also, many international members attend the annual meetings and serve on editorial boards and committees.

All members and institutions receive the Society's primary technical publication, the *Journal of Herpetology*, and its bulletin, *Herpetological Review*; both are published four times per year. Members also receive pre-publication discounts on other Society publications, which are advertised in *Herpetological Review*.

To join SSAR or to renew your membership, please visit the secure online ZenScientist website via this link:

http://www.ssarherps.org/pages/membership.php

Future Annual Meetings
2013 — Albuquerque, New Mexico, 10–15 July (JMIH with ASIH, HL, and AES)
2014 — Chattanooga, Tennessee, 30 July–3 August (JMIH with ASIH, HL, and AES)
2015 — Lawrence, Kansas, dates TBA

ABOUT OUR COVER: *Uromastyx benti*

Bent's Spiny-tailed Lizard (*Uromastyx benti*, Agamidae) is part of a species complex that is found in northeastern Africa. It was described in 1894 by John Anderson, a leader in Arabian herpetology, and named for British explorer and archeologist James Theodore Bent. This is a small species of *Uromastyx*, belonging to the *U. ocellata* group (Wilms and Schmitz 2007. Zootaxa 1394:1–23), and is found only in Yemen, southwestern Oman, and possibly in Saudi Arabia (Wilms and Böhme 2007. Fauna of Arabia 23:435–468).

Bent's Spiny-tailed Lizard prefers rocky, arid habitats, and unlike some of the larger *Uromastyx* species (e.g., *U. aegyptia*) that dig permanent, elaborate burrows in open gravel plains, this species lives in rock crevices and small burrows constructed under rocks. Like other *Uromastyx*, it is herbivorous. Listed as a CITES Appendix II species, *U. benti* is exported (largely from Yemen) for the pet trade. The magnitude of this export, as well as its effect upon local populations, is largely unknown. Fortunately, the rocky habitat home to *U. benti* is under little threat of development and seems to be stable (CITES, *Uromastyx benti*. <http://www.cites.org/eng/com/ac/22/E22-10-2-A6b.pdf>).

In Oman, this species was known only from the immediate vicinity of the coastal city of Mirbat (Seufer et al. 1998. Herpetofauna 20:22–23). However, on an expedition to the area in July 2011, Theodore Papenfuss and Todd Pierson discovered a pair near the Arabian Leopard Preserve at an elevation of 1410 m (Pierson and Papenfuss 2012. Herpetol. Rev. 43:491).

Todd Pierson recorded our cover image with a Canon EOS Digital Rebel XSi (450D) mounted on a tripod and using a Sigma 10–20mm f/4-5.6 wide-angle lens. Natural lighting was supplemented with a bit of fill flash from a diffused Canon Speedlite 430ex II mounted on camera (shutter speed of 1/200 second, f/13, and ISO 100). This large, colorful male was discovered basking on the rock over his burrow, which also held a smaller female. Pierson is an undergraduate in the Odum School of Ecology at the University of Georgia. He was awarded a scholarship at UGA that provided funding for international study, and during a three-year period, he has searched for amphibians and reptiles in England, Italy, Guatemala, Honduras, Nicaragua, Costa Rica, Oman, the UAE, Korea, and China.

SSAR BUSINESS

Roger Conant Grants-in-Herpetology Program 2013

Proposals will be accepted for the 2013 SSAR Grants-in Herpetology Program starting in September 2012. This program is intended to provide financial support for deserving individuals or organizations involved in herpetological research, education, or conservation. In keeping with the Society's goal of encouraging participation by the broadest possible community of applicants, preference may be given to individuals who might not have access to other funding sources. *Applications must be submitted by individuals only* (but see special considerations for education categories below).

Grant proposals will be considered in the following categories:

1. CONSERVATION OF AMPHIBIANS AND REPTILES. Proposals should outline a conservation-oriented research project. This project may focus on species endangered or threatened at the state, national, or international level, or address research on potentially threatened habitats or species, or on introduced injurious species.
2. THE ANDREW H. PRICE FIELD RESEARCH GRANT IN HERPETLOGY. Proposals may address needs for field station fees or equipment and materials in field oriented projects, or the field work portions of broader studies. This might include in-situ behavioral studies, ecological, life history, or sexual selection studies. Survey work by individuals or regional societies may be submitted here or in TRAVEL below depending on how the funds are to be used.
3. LABORATORY RESEARCH. Proposals may address needs for equipment or materials in laboratory projects or laboratory portions of broader projects. This might include studies in behavior, biochemistry, molecular biology, biomechanics, or physiology.
4. HERPETOLOGICAL EDUCATION. Proposals may address an educational project or start up support for an educational program in a zoo, museum, park, nature center, regional herpetological society, etc. The project must focus on a herpetological topic. *Note*: Although proposals for institutional projects are accepted, education proposals must be submitted by an individual (either sole applicant or principle contact person for the project). Applicants need not be students or SSAR member.
5. TRAVEL. Proposals may address support for travel to field study sites near or far, or to utilize distant collections or facilities. If funding is sought to get from one place to another, proposals should be submitted in the TRAVEL category. Proposals normally submitted in the CONSERVATION or FIELD RESEARCH categories should be submitted here if travel funding is being sought.
6. INTERNATIONAL. Proposals may address needs in any of the above five categories. The applicant must be a student, but not necessarily a SSAR member. Preference will be given to

CELEBRATING THE 7TH WORLD CONGRESS OF HERPETOLOGY

SSAR To Reprint the Herpetological Classic

ERPÉTOLOGIE GÉNÉRALE

ou Histoire Naturelle Complète des Reptiles

Constant Duméril

Gabriel Bibron

Auguste Duméril

AMONG THE PUBLISHED WORKS IN herpetology over the last five centuries, only two can be said to cover all known species of amphibians and reptiles comprehensively and scientifically. One, in English, was by George A. Boulenger and based on the collections of the British Museum in London (9 volumes, 1882–1896). These books were reprinted in 1961–1966 and, despite their age, remain among the most frequently consulted references in herpetology. The other, in French, was by Constant Duméril, Gabriel Bibron, and the senior author's son, Auguste Duméril, and based on the collections of the Muséum d'Histoire Naturelle in Paris (9 volumes plus an atlas of colored plates, 1834–1854). This latter work, generally known as "D & B," has never been reprinted, yet it remains of continuing value to a broad community of academic zoologists, museum and zoo curators, and conservationists, and especially to herpetologists working in developing countries. D & B is, in fact, more comprehensive than its English counterpart, for in addition to having more detailed descriptions of genera and species, it also covers the internal anatomy, physiology, and the associated literature.

Karl Patterson Schmidt, a leading American herpetologist, wrote: **"The *Erpétologie Générale* was the crowning work of a century of herpetological studies, during which the leadership in the field had lain with the French."** At that time, Paris was the epicenter of world science and its museum boasted the greatest naturalists: Buffon, Geoffroy Saint-Hilaire, Lacepède, Lamarck, and the greatest of them all, Georges Cuvier. Also among them was Constant Duméril, who trained as a physician and became one of Cuvier's closest colleagues. The Paris museum then possessed the largest natural history collections in the world. D & B was the first work in which a natural arrangement of genera was attempted, and many of the genera and species were first described there.

This full-size facsimile is absolutely complete and carefully edited for clarity. The 120 finely executed plates are reprinted in *both uncolored and colored states* because the original coloring sometimes obscures details of scutellation. The nine text volumes, which total more than 7,000 pages, and atlas of 120 plates are sturdily bound in library-grade cloth and printed on durable, acid-free paper. The **new introduction by Roger Bour (Paris)** is an in-depth review of the book (including exact publication dates) with new biographies of the three authors. A **comprehensive index to the scientific names**, missing in the original book, has been added. The original book was issued in fewer than 500 sets and is rarely offered for sale today. When it is, a colored set costs about US$15,000. (This reprint is being offered at an affordable price because of a generous subsidy from Ronald A. Javitch of Montréal.) Herpetological centers in developing countries are invited to contact the editor (*Kraig Adler*: kka4@cornell.edu) about special arrangements for obtaining copies.

■ *SPECIFICATIONS*: Nine volumes (bound in five) of text, plus an atlas volume of 120 plates (each in colored and uncolored states), all 5½ × 8½ inches (14 by 21.5 cm). Library-grade cloth bindings. ISBN 978–0–916984–87–8. ***To be issued November 2012***.

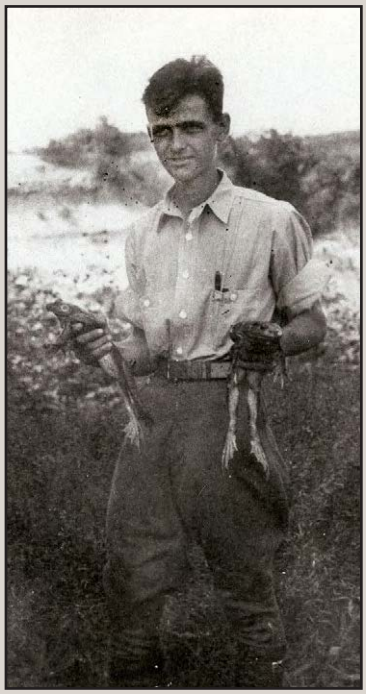
■ *PRICES*: • **Regular Price:** $275. • **Special Price to SSAR members** (if order is received before 31 December 2012): $225. • **Shipping**: USA address, add $15; non-USA shipping at cost. • **Orders to:** SSAR Publications Secretary, P.O. Box 58517, Salt Lake City, Utah 84158–0517, USA (*telephone and fax*: 801–562–2660; *e-mail*: ssar@herplit.com). • **Payment:** Make checks payable to "SSAR." Non-USA orders must be paid in USA funds using a check drawn on an American bank or by International Money Order. Books may be charged to American Express, Discover, MasterCard or Visa (please give account number and expiration date). • **SSAR Membership and Other Publications:** Membership information and a list of society publications can be obtained from the Publications Secretary at the address given above or at www.ssarherps.org.

students with limited access to research funds and in countries where herpetological research has historically been under-funded. **Note Regarding Eligibility in the International Category**: In late 2011, the current President of SSAR, the Grants-In-Herpetology Chair, and several members of the SSAR Board of Directors decided that proposals in this category would only be accepted if they were submitted from institutions OUTSIDE of the United States. Proposals from students who are primarily affiliated with United States institutions are *not* eligible for this category.

Submitting your proposal: All proposals must be submitted electronically to Joshua Kapfer (e-mail: kapferj@uww.edu) as a single PDF file named "lastname-category.pdf" no later than 15 December 2012 to be considered (letter of support may be included with the proposal or sent separately). Exceptions to electronic submission and file format may be allowed for special cases with prior approval by SSAR-GIH Chair. Full details about the GIH program and proposal requirements are available on the SSAR website: http://www.ssarherps.org/pages/GIH.php

Grants-in-Herpetology Donor Information

Financial contributions by SSAR members, institutions, and other benefactors support this program significantly, and can increase the number and/or size of awards. Your tax-deductible contribution (US citizens) to this program will directly benefit meritorious research and education in herpetology. Contact the Treasurer of SSAR for additional information about contributing to the Grants-in-Herpetology program. If you are employed by an organization that will match donations made to nonprofit organizations, please notify your employer that you have made a donation to the Grants-in-Herpetology program.



NEWSNOTES

Hobart Muir Smith Turns 100

Hobart Smith will celebrate his centennial birthday on 26 September 2012. In appreciation of Hobart's remarkable and unsurpassed contributions to herpetology, we invited a few of his colleagues and former students to offer comments.

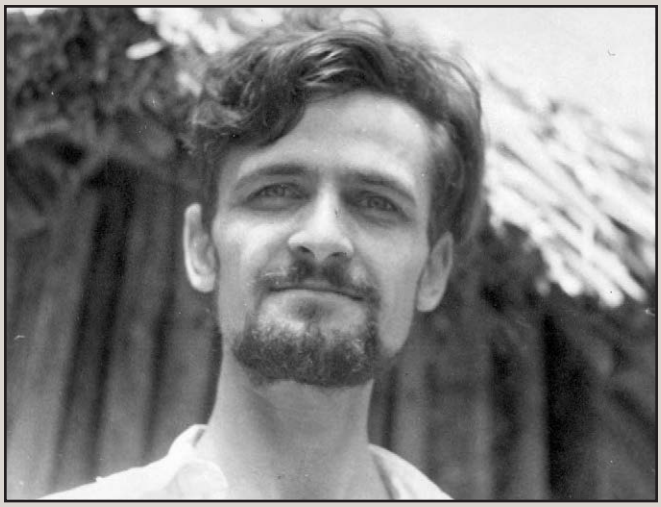
—R. W. Hansen, Editor

PHOTO COURTESY OF ALAN H. SAVITZKY

Hobart Smith with frogs in hand, 10 miles S of Austin, Texas, while in the field with Howard K. Gloyd, 24 June 1930.

Hobart: Over the years you have been kind, helpful, and generous. Sixty years ago when, as a student at Michigan, I visited Urbana to examine Mexican specimens in your collection, you always welcomed me. You and Rozella were kind enough to take me into your home in St. Joseph. There, we all watched Gunsmoke, you and I talked into the wee hours, and I shared a room with Bruce. Your extensive experience with the Mexican herpetofauna was a great inspiration to me. You told me where to look for some species and how to catch some others. I found it difficult to believe you when, upon my asking about the location of Cuautlapan in Veracruz, you told me to take the road from Orizaba to Córdoba and turn right in the middle of the bridge! A few months later (March 1956) I travelled that road, and sure enough there was a narrow gravel road descending from the middle of the bridge. If that were not enough, upon parking the carryall under a tree we asked a man if we could scour his surroundings looking for herps. The man replied: "Conoce el Doctor Smith y el Doctor Taylor?" [Do you know Dr. Smith and Dr. Taylor?] Standing before us was Carlos Cerón, who two decades earlier had guided you and Taylor in the area.

Over the years you have helped me in many ways, and I have learned much from you. But, most of all, I am proud to have developed a friendship over the past six decades. As you now have achieved a new apogee in your attainment of the century mark, you have set new goals for many of us "youngsters" who have come to respect and admire Hobart Muir Smith, a man whose perspicacity and generosity are exceeded only by his modesty.



William E. Duellman
University of Kansas, Lawrence, Kansas, USA

***

Almost 34 years ago I sent my first letter to Hobart Smith, in Spanish. I was asking for his help to obtain some publications that I was unable to find in Mexican libraries. His response was immediate. Since then, I have been corresponding with Hobart by letter and later by e-mail. Ten years after sending my first letter, I published a paper with Hobart, but our collaboration and friendship had started since I first wrote to him in August of 1978.

My relationship with Hobart has been very open and friendly, even though we do not agree in many fields of biology. We have talked about subjects other than Mexican herpetology—about politics, conservation, general science, and of course, Mexico. Throughout the years my relationship with Hobart became closer, until one day he sent an e-mail communicating to me his decision to donate his library to Mexico, in particular to Museo de Zoología, at UNAM. I made the arrangements to move Hobart's library, including logistic support, and raised the necessary funds. Our adventures

PHOTOS BY ROZELLA SMITH, COURTESY OF KRAIG ADLER

Smith outside his cabin at an archaeological site near Piedras Negras, Guatemala, May–June 1939.

Smith (left) and E. H. Taylor seining for *Ambystoma* salamanders in a pond about 12 miles NW of Toluca (Mex.), Mexico, September 1939. (This is from the only field trip to Mexico that Smith and Taylor made together.)

to move Hobart's library to Mexico were subsequently chronicled (Flores-Villela 2006. Bull. Chicago Herpetol. Soc. 41:225–227).

Although I did not study under Hobart's supervision, I have always considered him a mentor. Still these days, after he has retired from all professional activities, I e-mail him at least once a month, many times asking him about information regarding Mexican herpetology, or sending him manuscripts for his opinion. Hobart has been a very important person in my professional life and I have always received advice and support from him, and I am only one of many Mexican herpetologists Hobart has helped and advised. His dedication to Mexico has been the engine driving his many contributions to the study of Mexican species of amphibians and reptiles. I once wrote that Hobart Smith was the architect of modern Mexican herpetology, a title that no one can challenge and a status that still stands.

Oscar Flores-Villela
Museo de Zoología, UNAM, Mexico City

***

I had the good fortune of meeting Hobart when I came to do my graduate work at the University of Colorado (CU) in the late 1970s. Hobart was my advisor through 1981, and subsequent years were filled with many wonderful interactions. Above all, I've been astounded by his cheerful generosity. Even outside normal office hours, his door was always partly open, an invitation to anyone who might wish to talk with him. He always greeted visitors with a smile and enthusiastic welcome. It didn't matter if it was another faculty member, an undergrad, or a youngster bringing him a lizard or frog to identify. Seemingly, no visit was an intrusion or imposition. Later, when I came to Boulder to teach summer session courses, he proactively made sure I had plenty of space in his office/lab/magnificent library, and he even put me up in a room in his home, where I saw a new side of him (e.g., he simultaneously used his exercise bicycle, read a book, and watched football). A very few may have abused his unqualified generosity and trust yet—as kindness is another of Hobart's preeminent qualities—I never heard him utter a negative word about anyone.

His prodigious and amazingly long publication record is well known. Considering that I am now in my early 60s, it astonishes me to realize that he was publishing papers when my *parents* were still little children! His writing seemed effortless. While I struggled for weeks with a paper, he could write a finished paper in one day. And his prose is unique, particularly when unconstrained, such as in a book review, tribute, or obituary. I got so I could recognize his wonderfully distinctive style in an instant, without needing to see who the author was. Many of us who coauthored papers with him, with Hobart as a junior author, know a little secret. Once I confronted him with it: "Hobart, you wrote this paper, so why did you list me first and yourself second?" His response was that the discovery or idea was mine, so clearly I should be the senior author. I soon realized that almost all of those papers with Hobart listed as second or last author were in fact written by him.

Several years ago I participated in a reptile workshop in Jalisco, where my modest herpetological accomplishments understandably evoked only polite nods among the Mexican herpetologists. But when I happened to mention my connection with Hobart, faces instantly lit up with big smiles and exuberant testimonials. He quietly contributed to the endeavors of so many of us!

Hobart's era of maximum herpetological impact may have peaked before I met him, but not so his stature as a marvelous man and mentor. He never told me what to do or how to behave, but by example he showed the way. He engenders the affection of all who get to know him. During my years at CU, no one in the department was more beloved.

Geoff Hammerson
NatureServe.org

***

Hobart's influences over my academic/research development were many. I began working with him as a junior in college (1962) and stayed a student until I had finished my MS (1965). Surely his greatest influence was to propel me at *Eleutherodactylus*. He may have imagined that I would remain working on Mexican frogs but my appetites were already looking toward Ecuador and South America. In many ways, he induced me to tackle *Eleutherodactylus* with his praise to the effect that I had a taxonomic eye. Fifty years and some hundreds of *Eleutherodactylus* descriptions behind me, I must say that he was correct in his diagnosis.

He always claimed to know "nothing" about frogs (although he had described several from Mexico) and tried to compare me with his own major professor (E. H. Taylor). He likewise instilled

in me a serious respect for all the literature and that respect of what had been published has served me well these 50 years. We each delighted in detecting someone having read the literature superficially.

It is difficult, now 50 years later, to identify what other things he may have done, as a mentor, during those three years: for me, having encouraged me to tackle *Eleutherodactylus* and to respect (and to understand the context and to mine) the literature were his two greatest influences. During those three years, we published various things as coauthors and I learned much watching this dynamo at work and working directly with him.

Reflecting upon my career, I identify only a few professors playing crucial roles of raw encouragement: Hobart heads my list but is joined by George Byers (KU entomologist) and Philip Smith (herpetologist and ichthyologist of the Natural History Survey of Illinois). Byers almost convinced me to study hemipterans, Phil Smith almost convinced me to work on fishes, and Hobart set me upon my long path that ended up in Bogotá, Colombia.

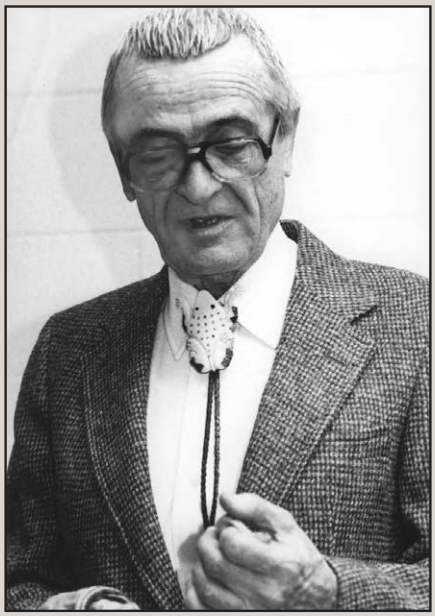


PHOTO BY KRAIG ADLER

Portrait of Smith with a small snake in his hand, dated about 1980.

His influence over my career was indirect but decisive. I recall now a seminar group to which he invited me to participate. We were dissecting a book by Sneath & Sokal (Numerical Taxonomy). Hobart expressed surprise that I found the book partly interesting while the other members of the seminar group thought it trash (for criticizing evolutionary taxonomy). Those debates led me to discover Willi Hennig and phylogenetic systematics; that discovery was crucial to my career development.

John D. Lynch
Instituto de Ciencias Naturales
of the Universidad Nacional de Colombia
Bogotá, Colombia

I had the great good fortune to be one of Hobart M. Smith's many graduate students. Smitty, as most students and friends called him, was a fantastic doctoral mentor. Under his tutelage, I learned a lot about doing research and a lot about life. As a doctoral mentor, I have tried to follow his example with my own students; and with less success, I have tried to adopt his view towards life. Three recollections of my interactions with Smitty during my graduate school days come to mind.

I was fascinated with vertebrate brains, particularly reptilian brains at the time, and I was trying to build a sizable collection of sectioned material. One day I went to Smitty and asked if there was any possibility of my obtaining one or two live tuataras. Amazingly, Smitty did not even ask what I wanted them for. Almost as surprising, in the context of today's grant-obsessed and "PI-driven" university environment, he did not indicate that his co-authorship would be required on any papers emanating from these animals. Instead, he simply said, "I'll see what I can do," and about a month later, two beautiful tuataras showed up on my desk.

On another occasion, I was in Smitty's office, ranting about a fellow graduate student, someone I believed had limited research ability and an obnoxious personality. Smitty listened patiently to my diatribe, and when I had finished, he smiled and said, "Glenn, did you ever consider that people are like crystals? Some have four sides, others eight, and some are even more complex." My first reaction was puzzlement: Why was Smitty talking about crystals? Finally, I realized I had just been taught an important lesson in life.

One day, when I was working in my student cubicle, Smitty came in and handed me the newly published translation of Hennig's *Phylogenetic Systematics*, with the comment that he thought I might be interested. As usual, he never asked what I thought of the book or made any attempt to discuss it. At the time, I did not know what to think of Hennig's revolutionary ideas, though I suspect Smitty had quickly discerned their heuristic value. It took me another few years to realize how critical phylogenetic systematics was to my own research, and even longer for Hennig's ideas to dramatically change the direction of my own research.

On the occasion of Smitty's 100th birthday, I salute him as a wonderful mentor, a good friend, and a remarkable human being. I only wish that Mary Sue and I could be present to help celebrate this occasion with him and his former students and friends. Happy Birthday, Smitty!

R. Glenn Northcutt

Like many young herp enthusiasts growing up in the U.S., Hobart Smith's Golden Nature Guide to reptiles and amphibians, written with Herbert Zim, was my first book on the subject. Even now a frayed copy sits in my home library, its iconic paintings burned into my memory from countless hours spent imagining my own encounters with those species. For a child growing up in Connecticut, the book's vivid tableaux, such as *Crotaphytus* running beneath sandstone mesas and *Farancia* inhabiting cypress swamps, only heightened the allure of herpetology.

Years later, as I was considering attending the University of Colorado, I learned by lucky coincidence that Hobart would be moving to CU the same year, following his early retirement from the University of Illinois. That news determined my choice of institutions, and shortly after my arrival in Boulder I arranged a meeting with Hobart. I immediately received his warm encouragement, as well as a key to his lab and his extraordinary herpetological library. Over the ensuing four years I worked for Hobart and Rozella on their bibliography of Mexican herpetology, pursued taxonomic projects with Hobart on *Tantilla* and *Sceloporus*, and joined the legion of students whom he encouraged to conduct field surveys in Mexico. I also took his comparative anatomy course, which sealed my interest in comparative morphology. Upon graduation Hobart encouraged me to attend his alma mater, the University of Kansas, and provided what I am told was the decisive letter, assuring my future graduate institution that I

was worth the risk, notwithstanding my undergraduate grades.

I graduated from CU exactly 40 years ago, and although my interests have led me far from the taxonomy of *Tantilla*, my research continues to be shaped by Hobart's influence. Known by colleagues primarily for his faunistic and taxonomic works, Hobart has had a broad range of herpetological interests. I have recently had the satisfaction of turning my own attention to a keen observation Hobart published when I was five years old, the enlargement of adrenal glands in *Heterodon*. We now know that this intriguing condition occurs in several other toad-eating snakes, although its significance remains to be elucidated.

More than his research itself, however, Hobart's students know that his defining characteristic is his compassion, from which springs the encouragement he has given to several generations of young herpetologists. I am certain that many of Hobart's former students, like myself, continue to find themselves guided in their professional lives by his exemplary mentorship.

I enrolled in comparative anatomy at the University of Illinois in the spring of 1954 under Hobart. I received a "B" and was delighted. However, difficulties in English and algebra put me on probation. I volunteered for the draft that summer and entered the Army. Eventually I ended up at Fort Bliss in El Paso, Texas. I was visiting the Post library when I came across a copy of "Lizards of the United States" by a guy by the name of Hobart M. Smith. I had the common childhood interest in reptiles, which had persisted, and thus I was intrigued by the book. I soon found that the El Paso area had numerous lizard species. I wrote Dr. Smith asking if he would be interested in specimens from the area and received a two-page reply indicating indeed he was, and since I was so close to Mexico why not explore the dunes south of Juarez. Needless to say I was ecstatic hearing from someone who had written a book and who had invited me to collect and come see him when I returned to Illinois. Thus began a long and cherished association with Dr. Smith. His patience with me in dealing with my poor writing skills and working my way to first a B.S. degree and then a M.S. at the University of Illinois were undoubtedly something no other professor would have done.

In retrospect, he is one of two people who are responsible for me accomplishing my professional career. My wife would be the other, without whose support it never would have happened. There are others along the way who have improved and aided me, but there is no doubt in my mind had I not had the luck to "stumble across" Hobart my life would be dramatically different.

In conclusion, I must mention that in a recent historical perspective on HMS (Chiszar et al. 2004. Copeia 2004[2]:418–424), I was dumbfounded to be mentioned with the likes of Glenn Northcutt and Karel Liem as the graduate students he was "in awe" of.

Happy 100th, Dr. Smith! The year was 1960. I had transferred to the University of Illinois after two years at Millikin University in my hometown of Decatur, Illinois. By then, I had committed to working with ectothermic vertebrates, but began by developing an interest in fishes. It only took one course, however, under Dr. Hobart M. Smith, Comparative Vertebrate Anatomy, to shift my academic direction toward herpetology. It was his dynamism and outgoing nature that did the trick, as well as his production of a hugely significant body of work on the amphibians and reptiles of Mexico, that exotic land on the other side of the border. When I decided to pursue graduate education in herpetology, with my sights set on the American tropics, it was Hobart Smith who suggested the schools to which I should apply. That act, surely so simple for him, was what set the stage for all that has followed and I credit him as my principal mentor during my career.

With the onset of the 70s, our paths crossed professionally when I began to work on *Tantilla*. Smith's seminal 1942 study on Mexican *Tantilla* is the beginning point for serious systematic study of these small snakes. Of the 63 currently recognized species in this genus, Smith is responsible for naming more than 10% of them.

In 1983, I had a chance to acknowledge my debt to Hobart Smith when I organized a symposium in his and Rozella's honor held at the annual SSAR meeting. A number of prominent herpetologists working in Mesoamerica participated in that event. The paper I co-presented then finally appeared in 1987.

Hobart Smith's influence is still felt in my recent work, especially in the book *Conservation of Mesoamerican Amphibians and Reptiles* (2010). The longest chapter in this book, written by Jerry Johnson and I, cites 14 papers authored or coauthored by him and his name sits in the Acknowledgments.

I know I am only one of many people who are indebted to Dr. Smith in ways small and large. For me, however, his influence determined the direction of my career and, in a significant way, the nature of the contributions I have made to our field.

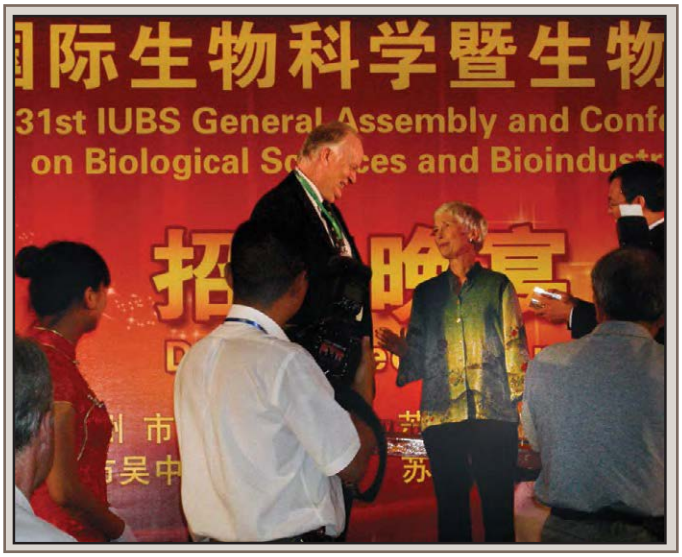
Charles Stearns Grant-in-Aid for Herpetological Research at the California Academy of Sciences

The Section of Herpetology is pleased to provide limited financial aid—mostly to cover transportation and limited per diem expenses—to graduate students who wish to visit our collections to support research on amphibians and reptiles.

Proposals should include a short, one-page description of the research project, a budget, and a letter of support from the student's faculty advisor.

Applicants are encouraged to access the database of CAS amphibian and reptile holdings before writing their proposal. Access



to the database could be found at http://research.calacademy.org/herp

Proposals are due on 30 October 2012, with notification by 1 December 2012. Grantees are expected to complete their Academy visit by 30 September 2013. Please call 415-379-5277 or email mhoang@calacademy.org for further information.

Send proposals—a single PDF document containing the proposal, budget, and letter of support— by email to mhoang@calacademy.org.

IUBS Honors Marvalee Wake

PHOTO BY DAVID B. WAKE

At the 31st General Assembly of the International Union of Biological Sciences, held in Suzhou, China in early July, 2012, Professor Marvalee H. Wake, of the University of California at Berkeley, was presented with the Inaugural IUBS Award "in recognition of her dedicated and meritorious contribution to the IUBS and to Biological Sciences." Professor Wake began her association with IUBS as a member, and then Chair, of the US National Committee of IUBS. She was elected Secretary-General of IUBS, located in Paris, in 1994 and served until 2000, when she was elected President, serving from 2000 to 2004. She was Past-President from 2004 to 2007, and has remained active in the organization. During her Presidency she inaugurated the scientific program "Towards an Integrative Biology," and she has been an articulate international spokesperson for development of integrative biology. She was the founding Chair of the Department of Integrative Biology at the University of California at Berkeley, starting in 1990.

Brett Stearns Award for Chelonian Research at the California Academy of Sciences

The Section of Herpetology is pleased to provide limited financial aid—mostly to cover transportation and limited per diem expenses—to researchers who wish to visit our collections to support their work in chelonian biology. Preference will be given to graduate students.

Proposals should include a short, one-page description of the research project and a budget. In the case of graduate students, a letter of support from the student's faculty advisor is required.

Applicants are encouraged to access the database of CAS chelonian holdings before writing their proposal. Access to the database could be found at http://research.calacademy.org/herp

Proposals are due on 30 October 2012, with notification by 1 December 2012. Grantees are expected to complete their Academy visit by 30 September 2013. Please call 415-379-5277 or email mhoang@calacademy.org for further information.

Send proposals—a single PDF document containing the proposal, budget, and the letter of support in case of graduate students— by email to mhoang@calacademy.org.

David J. Morafka Memorial Research Award 2013

In honor and memory of Prof. David J. Morafka, distinguished herpetologist and authority on North American gopher tortoises, the Desert Tortoise Council, with the aid of several donors, has established a monetary award to help support research that contributes to the understanding, management and conservation of tortoises of the genus *Gopherus* in the southwestern United States and/or Mexico: *G. agassizii, G. morafkai, G. berlandieri,* and/or *G. flavomarginatus.*

Award Amount: US $2,000 to be awarded at the Desert Tortoise Council's Annual Symposium, depending on the availability of funding and an appropriate recipient.

Eligibility: Applicants must be associated with a recognized institution (e.g., university, museum, government agency, non-governmental organization) and may be graduate students, post-doctoral students, or other researchers. They must agree to present a report on the results of the research in which award funds were used at a future symposium of the Desert Tortoise Council.

Evaluation Criteria: Applications will be evaluated on the basis of the potential of the research to contribute to the biological knowledge of one or more of the above gopher tortoise species, and to their management and conservation. Important considerations are the significance and originality of the research problem, design of sampling and analysis, preliminary data supporting the feasibility of the research, and the likelihood of successful completion and publication.

Application Procedure:

1. Download an application form from the Desert Tortoise Council's website: www.deserttortoise.org.

2. Provide all information requested on the application, including a description of the research project in no more than 1,200 words.

3. Submit the completed application to grstewart@csupomona.edu as a pdf attachment.

4. Applications must be supported by three letters of recommendation, one of which must be from the applicant's research

advisor, supervisor, or a knowledgeable colleague. Instruct the recommenders to submit their letters to grstewart@csupomona.edu as pdf attachments.

5. Completed applications and letters of recommendation must be received by **December 3, 2012**. They will be evaluated by a committee of gopher tortoise biologists appointed by the Desert Tortoise Council Board of Directors.

6. The research award recipient will be notified of his/her selection by **January 18, 2013** and the award will be presented at the 2013 Desert Tortoise Council Symposium, February 15–17, 2013.

New from PARC

Partners in Amphibian and Reptile Conservation (PARC) is pleased to announce that the newest edition of our popular and award-winning series, the PARC Habitat Management Guidelines (HMG), is now available! *Habitat Management Guidelines for Amphibians and Reptiles of the Midwestern United States* book is ~150 pages of full-color, practical, and proactive guidance for improving the compatibility of land management practices with these animals.

• WHAT do the HMGs have to offer?
These guides provide peer-reviewed, recommended management practices for amphibians and reptiles, along with alternatives when the ideal scenario is not possible.

• WHY are the HMGs useful?
They can inform individuals and agencies how to adapt their land management decisions to include herpetofauna, particularly in cases where they are not sure how best to begin. The HMGs are standardized in order to be applicable across regions.

REMINDER: The Southeast, Northeast, and Northwest regional guides are still on sale at 50% off (US $5.00). This price includes shipping, except to international destinations. See our HMG page (http://www.parcplace.org/publications/habitat-management-guidelines.html) for ordering information. All proceeds go to the production and printing of future HMGs and other PARC products such as these, never to operating expenses.

Also, keep checking back for our Southwest HMG—the last in our US-based regional series—currently in progress; it can be pre-ordered at the regular price of US $10.00 per copy.

MEETINGS

Southern California Association of Professional Herpetologists

The first meeting of SCAPH (Southern California Association of Professional Herpetologists) occurred at the Desert Studies Center (a field station of California State University) in Zzyzx, San Bernardino County, California on 8–9 June 2012. After socializing and some road patrolling on Friday, Saturday was spent on introductions, short presentations by those who wanted to talk about their research, and a discussion of the future of the group. We thank Bill Presch and others at the Center for their hospitality and Bobby Espinoza for spearheading organization of SCAPH and the trip.

Red Listing Central American Squamates

Reptiles are conspicuously absent from the list of taxa that have been comprehensively assessed worldwide for extinction risk through the IUCN Red Listing process. Unassessed species are frequently overlooked in conservation planning exercises, and often ineligible for international assistance for conservation efforts. Although most North American reptiles have been assessed, there are big gaps for the diverse Latin American fauna. To begin to rectify the situation, a group consisting of NatureServe, Universidad de Costa Rica, Organization for Tropical Studies, IUCN, Fundazoo, CBSG Mesoamerica, and independent scientists co-convened a workshop to complete Red List assessments for Central American squamates. The goal was to review existing and create new Red List assessments for all species of Central American squamates, including threat category assignment, the compilation of supporting data, and the creation of range maps.

The workshop took place 6–10 May 2012, and involved 34 invitees, all either herpetologists with experience studying Central American reptiles in the field or scientists knowledgeable about the IUCN Red List criteria and database who served as facilitators of working groups. Rather than hold the workshop at a hotel conference room or university setting, the organizers chose to bring the participants to the Palo Verde Biological Station, located within Palo Verde National Park in Costa Rica. This tropical

dry forest location proved to be an exciting backdrop for a rather intense week of compiling data and assigning Red List criteria.

The workshop began with an introduction to Palo Verde and the project, followed by a thorough review of Red List criteria and the sometimes non-intuitive terms used in the Red List documentation. The remaining 4.5 days were spent in small working groups, arranged geographically, reviewing the assessments for each species. The groups began by focusing on single-country endemics and gradually coalesced to address bi-national and regional species. A separate group worked all week on widespread species in Central America. Thanks to heroic efforts, several late nights, and the lure of certain sugar cane-derived beverages as rewards at the end of each day, the assembled scientists succeeded in working through 468 currently recognized species of squamates native to Central America.

The formal IUCN process requires external review (in fact herpetologists with knowledge of Central American species who did not attend can expect to be contacted shortly to contribute in this regard), so the workshop results are preliminary. Nevertheless, there is a strong indication that nearly a fifth of the Central American squamate species are threatened with extinction. Many of these are endemic northern Central American lizards and snakes restricted to isolated cloud forests that are rapidly being destroyed by the advancing agricultural frontier. In many cases, personnel at designated protected areas simply do not have the wherewithal to hold the line against this onslaught of habitat destruction. Another observation made while looking around the room of assembled scientists is the paucity of female herpetologists working on the Central American reptile fauna. The field needs to diversify and actively attract women, especially Central American natives, to contribute to the considerable task of discovering, describing, and learning about the natural history and population status of these fascinating animals.

Why the focus on squamates and not all reptiles? IUCN specialist groups for freshwater turtles, sea turtles, and crocodiles have already assessed species in their purview. For the squamates, the viper, iguanid lizard, and anoline lizard specialist groups have made varying levels of progress at assessing species they cover, but none was complete for Central American species. The remaining lizards and snakes, making up the bulk of the reptiles, are not covered by an existing specialist group.

The workshop coincided with the first rains of the rainy season at Palo Verde. Afternoon downpours brought out toads, many of which had been inactive underground for months, frogs, as well as snakes eager to dine on the batrachians. The assembled regiment of herpetologists, some sacrificing measurable quantities of blood in the effort, succeeded in recording 24 reptile and 13 amphibian species during field forays organized around the margins of the meeting. Although the snake diversity and abundance was impressive, an emergence one evening of *Rhinophrynus dorsalis*, at the southern edge of its range in Palo Verde, stole the show for many.

Now that the workshop is concluded, the facilitators will upload the assessments to IUCN's central database, tie up any remaining loose ends on the accounts, and digitize the corrected range maps. The IUCN snake and lizard red list authority will then obtain two external reviews for each species account. After adjusting the accounts in accordance with the reviews and final quality control, they will be published on the IUCN Red List website. GIS files for the range maps will be available for download on the same site. A summary manuscript of the results is also planned for submission to a scientific journal. Similar workshops are planned for 2013–2014 to work through assessments of the Caribbean and South American squamates.

FIG. 1. Participants at the Central American Squamate Red List Workshop, held 6–10 May 2012 at Palo Verde National Park, Costa Rica. Standing (left to right): Phil Bowles, Erick Ballestero, Joseph Vargas, Quetzal Dwyer, Ileana Luque, Joe Townsend, Guido Saborío, Jerry Johnson, Mahmood Sasa, Javier Sunyer, Bill Lamar, César Jaramillo, Yolanda Matamoros, Roberto Ibáñez, Marcelo Tognelli, Bruce Young, Randall Arguedas, Geoff Hammerson, Louis Porras, José Hernández. Not shown: Manuel Acevedo, Federico Bolaños, Neil Cox, Adrián García.

PHOTO BY PHIL BOWLES

FIG. 2. This *Leptophis mexicanus*, assessed as Least Concern, was one of 24 reptiles recorded by participants when not in their working groups.

The success of the workshop is due in equal parts to the convening organizations and the scientists (including some who were not able to attend but sent observations and distribution maps nonetheless) who so cheerfully contributed their knowledge, experience, and sweat to the project. Each organization contributed financially to the event, as did a National Science Foundation grant to NatureServe (DEB-1136586). The Palo Verde

Field Station was an ideal site for the event, combining comfortable facilities, delicious food, and interesting natural history observations right outside the meeting room doors (and sometimes even inside the doors). These contributions will help set the stage for stepped up efforts to conserve the remarkably diverse and sometimes critically threatened squamate fauna of Central America.

—Bruce E. Young, NatureServe, 4600 N. Fairfax Dr., Floor 7, Arlington, Virginia 22203, USA

Meetings Calendar

Meeting announcement information should be sent directly to the Editor (HerpReview@gmail.com) well in advance of the event.

4–6 October 2012—34th Annual Gopher Tortoise Council Meeting, Bainbridge, Georgia, USA. Information: www.gophertortoisecouncil.org/events.php

24–27 October 2012—Southwest Partners in Amphibian and Reptile Conservation (SW PARC) annual meeting, Las Vegas, Nevada, USA. Information: www.swparc.org/meetings.html

2–4 November 2012—Kansas Herpetological Society 39th annual meeting, Sternberg Museum of Natural History, Fort Hayes State University, Fort Hays, Kansas, USA. Information: http://cnah.org/khs/AnnualMeetingInfo.html

6–9 November 2012—XII Reunión Nacional de Herpetología, Sociedad Herpetológica Mexicana, Tuxtla Gutierrez, Chiapas, Mexico. Information: http://www.sociedadherpetologicamexicana.org/noticias/index.php

20–23 May 2013—World Crocodile Conference, 22nd Working Meeting of the Crocodile Specialist Group IUCN-SSC, Colombo, Sri Lanka. Information: www.csgsrilanka.com

OBITUARIES

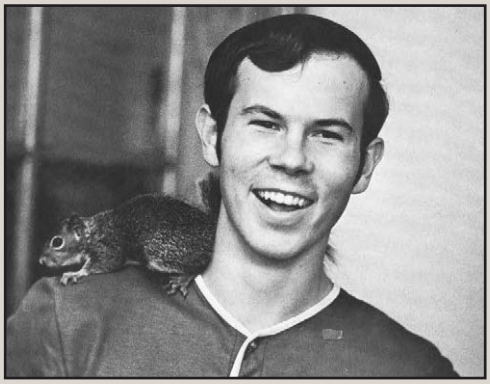
Herpetological Review, 2012, 43(3), 370–375.
© 2012 by Society for the Study of Amphibians and Reptiles

In Memoriam: Andrew Hoyt Price (1951–2012), with Reflections from Colleagues and Friends

On 16 January 2012, herpetology lost one of its most dedicated and active professionals. Andrew Hoyt Price, age 60, succumbed to a long and courageous battle with multiple myeloma. He was born on 12 May 1951 in Brussels, Belgium, to his parents, C. Hoyt of Arkansas (USA) and Rosemary Price of England. Andy's father was a U.S. diplomat, so he grew up mostly abroad in Belgium, Vietnam, and Switzerland, with rotations in and out of Washington, D.C. He is survived by two brothers, Carl Price of Chandler, Arizona, and Roger Price of Pittsburgh, Pennsylvania. Andy's son, Alexander Hoyt Price, lives with his wife and Andy's two grandsons in Lovington, New Mexico.

PHOTO BY DEAN HENDRICKSON

Andy Price at the Texas Natural History Collections, Austin, 2009.



Andy's development as a biologist began with his Bachelor of Science in biology degree from the University of Miami in 1973. During 1973–1974, he spent a year in the sections of Mammalogy and Amphibians and Reptiles at the Carnegie Museum of Natural History in Pittsburgh, Pennsylvania. His job was to conduct vertebrate faunal surveys of the Allegheny County Regional Park System. At Carnegie, Andy found a life-long friend and mentor in C. J. (Jack) McCoy, curator of the herpetology section.

Although his academic interest was initially with mammals, Andy's childhood fascination with reptiles soon took over. Like many herpetologists, his interest for reptiles started at a young age. "When we cousins were playing together at our grandparents' farm, and someone yelled, 'Snake!' we all ran. The rest of us toward the house, Andy toward the snake." (From the eulogy by his cousin, Rev. Robert Price). After Carnegie, Andy spent the following three years at New Mexico State University (NMSU) working on scent glands in *Lampropeltis getula splendida* for his Master of Science degree under his advisor, the late Joe LaPointe (Price 1978; Price and LaPointe 1981). He remained at NMSU and completed his Ph.D., focusing on competition and parthenogenesis in whiptail lizards (*Cnemidophorus*, now *Aspidoscelis*; Price 1986a, Price 1992, Price et al. 1993). After graduating, he worked as a wildlife biologist with the U.S. Bureau of Land Management from 1980 to 1981. There he conducted herp, bird, mammal, and vegetation surveys of the Jornada Resource Area, Socorro District, New Mexico, as well as general surveys in other areas. In late 1981, he worked with the New Mexico Natural Heritage

WENDY L. HODGES
e-mail: wendyLhodges@alumni.utexas.net

Program to computerize plant specimen data in the university herbarium. Throughout his entire time in New Mexico, Andy served as the assistant curator of herpetology at NMSU.

After completing his Ph.D. in 1986, he worked briefly for the Office of Quality Assurance at Holloman Air Force Base, New Mexico, where he was responsible for data auditing and study inspections to ensure compliance with FDA and EPA guidelines. His experience with the New Mexico Natural Heritage Program and knowledge of regulations helped him land a job as staff zoologist with the Texas Natural Heritage Program in Austin, Texas, in late 1986. Andy was often referred to as the "State Herpetologist" during his tenure at TPWD. His job required him to fulfill the usual state bureaucratic obligations including wildlife and scientific permitting, but he was adamant that he would perform his job with scientific objectivity and continue active participation in research whenever possible. He was responsible for monitoring the rare and endangered fauna of Texas and planning, administering, and conducting field surveys to determine their status. He doggedly pursued funding for these activities through Section 6 of the Federal Endangered Species Act and any other resources he could find. He aided development and review of conservation policy for the state, including a database abstracting the ecological characteristics of Texas vertebrates, conducted research, guided education, and provided technical guidance concerning the herpetofauna of Texas. His major research projects included long-term ecological monitoring, educational activities, and development and implementation of a habitat conservation plan for the Houston Toad (*Bufo houstonensis*) (Price 2003; Hatfield et al. 2004); phylogenetic studies of turtles in the genus *Trachemys*; a status survey of the Texas Horned Lizard, *Phrynosoma cornutum* (Donaldson et al. 1994); and the distribution, systematics, phylogeny, and conservation status of hemidactyliine plethodontid salamanders (Chippindale et al. 1993, 1998, 2000; Chippindale and Price 2005).

Andy befriending a squirrel (from his high school yearbook, 1969).

Andy's scientific objectivity did not always agree with TPWD administrators. He began state employment at a time when conservation issues were increasingly challenged politically, and the economics of conservation decisions in Texas were influencing the biology and science of rare and endangered species. Conservation of the Barton Springs Salamander (*Eurycea sosorum*), which lives only in the center of Austin, was one project that showcased these challenges. Andy was assigned to work with a team of four scientists over several months. Their tasks included taking field trips to the springs and other localities of related salamanders, conducting flyovers of the area, studying many documents from several agencies on water quality, regional hydrology and land use, and then combining it all into a comprehensive report. During this time period, the state dissolved Andy's title as Endangered Species Biologist and also eliminated the state biological survey. The politics at federal, state, and local levels were intense and covered regularly in the Austin press. Real estate developers hired lobbyists, lawyers, and their own consultants to fight anything in the report that might curtail their plans along the Edwards Aquifer recharge and contributing zones, some of the most valuable and environmentally sensitive property in the state. Despite their efforts, the city adopted the main recommendations of the scientific study team. Andy was indefatigable in his work on the project. His knowledge of the species' biology, conservation issues, and commitment to what he saw as his job was truly professional. The salamander was later listed as federally endangered (U. S. Fish and Wildlife Service 1997).

Andy retired from TPWD in 2008 after 22 years of state service. His first battle with multiple myeloma occurred while he was still employed. He was originally diagnosed in the summer of 2006 and had a bone marrow transplant in March 2007. He was in remission by the time he retired from TPWD and actively continued to work and fulfill professional obligations until it reappeared in mid-2010. During 2009–2010, he was a curatorial assistant in the Texas Natural History Collections at the University of Texas, Austin, and a part-time assistant professor of biology at Southwestern University in Georgetown, Texas, where he taught environmental science and ecology. From 2009 until his death, he was a scientific advisor for the Texas River Systems Institute, Texas State University. He also contracted with local biological consulting companies to work with sensitive, rare, and endangered species.

In 1994, Andy received the George Miksch Sutton Award in Conservation Research by the Southwestern Association of Naturalists (SWAN) and, in 2008, a Lifetime Achievement Award from the Texas Herpetological Society, Horned Lizard Conservation Society, and Southwestern Partners in Amphibian and Reptile Conservation. The Sutton Award from SWAN was for a paper he co-authored on the distribution and status of the Devils River Minnow, *Dionda diaboli* (Garrett et al. 1992). He was especially proud of his 26-year appointment as a research associate with the Section of Amphibians and Reptiles, Carnegie Museum of Natural History.

Andy's commitment to numerous state, national, and international professional societies reflected his dedication to the profession and love of natural history literature. At the time of his death, he was a member of 19 societies. Throughout his career, Andy served the professional herpetological societies in numerous ways. Notably, he served as Associate Editor for the *Journal of Herpetology* (1994–1996), Treasurer for The Herpetologists' League (1988–1993), Associate Editor of herpetology for American Midland Naturalist (1994–1997), and General Herpetology Editor for Copeia (1997–2000).

Andy was a bibliophile and especially adept at uncovering literature on herpetological topics. His lifelong goal was to have a hard or electronic copy of every known publication on lizards. His love of the literature and dedication to herpetology were reflected by his 26-year tenure with the *Catalogue of American Amphibians and Reptiles* (CAAR) series published by SSAR. He was the Sauria and Amphisbaenia section editor beginning in 1987 and editor-in-chief as well from 2005 until his death. He knew the literature so well that he frequently added citations to CAAR accounts missed by the authors. As Bob Powell noted, "It was a bit daunting when you thought you'd done everything only to have him send a list with another 10+ citations you hadn't seen." He authored or coauthored seven species accounts in this series

(Price 1980, 1982, 1986b, 1990; Price and Sullivan 1988; Bell et al. 1996; Thompson et al. 1998). Andy's last actions were to make recommendations to SSAR about the future of this publication series.

Andy was able to produce a steady stream of contributions to herpetology while working a state job that did not require him to publish. Between 1978 and 2008 he presented or co-presented two dozen papers at annual herpetology meetings, Texas herpetological societies, and in invited symposia. Andy's co-authored book, *Amphibians and Reptiles of New Mexico*, with Bill Degenhardt and Charlie Painter (Degenhardt et al. 1996), is the definitive treatise on this topic. Indeed, the authors received a Southwest Book Award for Literary Excellence in 1998 by the Border Regional Library Association (El Paso, Texas). Andy wrote two editions of a popular book on Texas snakes (Price 1998, 2009). At the time of his death, he was working on a compilation of literature on herpetological remains associated with Native American activities in North America and a summary of the conservation biology of the Houston Toad (*Bufo houstonensis*). Two field projects in which he was interested, taxonomy of salamanders in the genus *Siren* and distribution and ecology of the Rough-footed Mud Turtle (*Kinosternon hirtipes*) in Texas, were cut short by his untimely death.

Contributing substantially to one's profession is hard enough while working at an academic institution where there are such expectations. Being active in professional societies and consistently producing publications throughout one's career while working for a state government agency is exceptionally rare. Andy will be remembered for his life-long dedication to and support of the science of herpetology.

Recollections of Andrew Price

It has been my privilege to know Andy Price for several decades, almost from the time he earned his Ph.D. His knowledge of and contributions to herpetology have been multiple, but with a focus on lizard systematics and natural history. Others have duly noted these aspects of his career in this tribute. Instead, I want to comment on his service contributions to herpetology.

Every scientific society owes its existence to a relatively small handful of altruistic individuals who regard voluntary service to their profession as obligatory payback. Without them—the officers, editors, committee chairs, and meeting organizers—there would be no scientific societies, which are essential to the development of any scientific discipline. SSAR is no different from other societies, but has been blessed with an unusually large number of such individuals. Andy Price is a prominent example. His service to SSAR began in the usual way—as a member of various committees. In 1987, only a year after receiving his doctorate, he became Section Editor of Sauria and Amphisbaenia for the *Catalogue of American Amphibians and Reptiles*, which was to become the primary focus of his service contribution to the herpetological community. With his unusually broad knowledge of these reptiles, he was the ideal person to edit this section because he knew the right people to choose as authors and reviewers, and he then improved their contributions with his painstaking and informed editing. In 2005, he was promoted to Editor-in-Chief of the entire *Catalogue* and continued the high editorial standards of his predecessor, Bob Powell.

Through this editorship, Andy became fully invested in SSAR. He recognized that the success of his serial was dependent on the overall success of the society and was therefore an active participant at meetings of the Board of Directors. He got involved in almost every discussion and on a wide range of topics. Because of the quality of his editorial work and his clear thinking on so many topics, he was highly respected around the table. He continued to edit the *Catalogue* and attend Board meetings even while suffering through his final illness. Last year, the officers and editors of SSAR presented him with a signed and framed "Certificate of Recognition" for his editorship of the *Catalogue* and his many years of service to the herpetological community. His devotion to his colleagues and his discipline set a very high standard, but Andy did it because he thoroughly enjoyed editing and his other work within SSAR. I think he regarded these activities among the crowning achievements of his professional life. I certainly do.

I met Andy Price in the fall of 1989 when I was a new graduate student in David Hillis' lab at UT Austin. Andy was the state herpetologist, and he and David had various collaborations in progress. Among these was a study of the enigmatic Texas cave and spring salamanders (*Eurycea* and what was then *Typhlomolge*). The group had been problematic for decades in terms of systematics and taxonomy, was rapidly becoming a major priority for conservation, and a molecular approach was essential to sort it all out. Until shortly before my arrival, David had a student who was working on this with him and Andy, but he suddenly and mysteriously disappeared (he briefly reappeared a few years ago, but that's another story). Mystery and intrigue have been a longstanding part of the Texas *Eurycea* investigation that was so much a part of our lives.

I had all sorts of ideas about Ph.D. projects, but David, although wide-open to various possibilities, was especially eager to see me tackle this one. He and Andy and I dived into fieldwork almost immediately after I arrived, and I quickly became fascinated with the group. There was no question that I'd pursue it, but I still had doubts as to whether this would be my major project. I think it was Andy who finally cemented it in my mind; he told me that I'd be crazy to pass up the opportunity, that there was enough there for multiple dissertations, and that chances like this don't come up every day. Initially I had found Andy a little distant and perhaps even cold, but nothing could be further from the truth. He and I rapidly became not only close collaborators, but also close friends. He was an invaluable field companion who made possible access to many very difficult sites (springs and caves, including some of the most uncomfortable caves you can imagine). Andy also was key in helping to secure funding from Texas Parks and Wildlife Department, U.S. Fish and Wildlife Service, and National Science Foundation that allowed us to carry out this potentially daunting study on a major scale. And throughout, he was a major inspiration for my research.

As my molecular results started rolling in, the situation turned out to be even more complex (and politically charged!) than I ever would have expected. I sometimes found this a bit overwhelming, but Andy's usually calm and practical demeanor (simultaneously a complement, but also a contrast, to David's boundless yet occasionally over-the-top enthusiasm) was a tremendous help. This was especially critical for me when Andy and I were involved in a tragic accident in which a military police officer who

was escorting us in a search for cave salamanders fell to his death, right in front of me. Andy's support when it happened, and later, when I kept questioning whether there was something I could have done to prevent it, made a huge difference. In retrospect, things like this just happen sometimes, but back then, Andy really helped me come to terms with it, practically and emotionally.

Andy, although often stoic and tough, also had his share of problems. He sometimes tried to do everything. I have no idea, for example, how many thousands of hours he put into his meticulous, multi-year tracking studies of Houston Toads. He often became frustrated by the sheer volume of work, the politics, the bureaucracy of it all, yet he maintained his drive and enthusiasm, and dedication to study and conservation of amphibians and reptiles. I'm glad that, especially as I matured as a scientist and a person, I was able to provide support and reassurance to him as he did for me. Over the years, Andy became one of my closest and most trusted friends, and our respect and help for one another extended far beyond the scientific arena. He made a huge and permanent difference in my life.

Even now, almost 23 years after I started as a Ph.D. student at Austin and first got to know Andy, others and I still use specimens and samples that we collected, and refer to his field notes, morphological data, and other information, much of which would be unobtainable now. There's still more work to be done, there are yet more species of Texas *Eurycea* to be described, and his contributions and insights are playing an integral role. Even though Andy is gone, he left an invaluable legacy, both scientific and personal, for so many of us and for preservation of the biodiversity that he loved.

***

My remembrances of Andy go back to his graduate school days. He was much younger at the time, but a curmudgeon even then. While he was at New Mexico State University, he read one of my papers on the White Sands lizards and suggested I may have misidentified one of the species. One of my graduate students was also working on the same genus, and he and I thought we would play a joke on Andy without even knowing his personality (a mistake on my part). A letter was sent to Andy suggesting that he challenged my ability to recognize such a well-known species and he should get help from a local taxonomic expert about his own ability to recognize the species. This started a series of letters between Andy and me. You have to remember there were no computers, and letters required about a two-week turnaround time. Andy's third letter was so apologetic that I was afraid I had ruined his graduate career. I sent another letter apologizing for my original response, stating that I was trying to have some fun with him. We met later at a SWAN meeting and Andy and I had a laugh about it, but I realized that Andy was very serious about his science and I should tread lightly on this subject.

Following Andy's graduation and his employment with TPWD, Andy and I became friends and colleagues. I made several trips with Andy to Bastrop State Park, especially "ponds 9 and 10," where we marked a number of Houston Toads in the late 1980s. I also met several times with Andy in Presidio County where we met Dennie Miller at a study site for the Rough-footed Mud Turtle. Dennie and I always joked with Andy about his passion for obscure critters like Houston Toads and Rough-footed Mud Turtles. I finally found that Andy did have a dry sense of humor, but it took some time to bring it to the surface.

I believe Andy was a curmudgeon from day one, and that was a part of his personality that we all learned to deal with. Andy would sometimes explode angrily, but if you listened and let him work it out of his system, he became the loveable curmudgeon we all enjoyed and admired. We all miss Andy, and especially the loveable part!

I first met Andy when I was working at The Nature Conservancy International (1986). I had to travel from Washington, D.C. to Austin, Texas, to spend a two-week internship with the local Natural Heritage Program where Andy worked. The first day I arrived at the Texas Natural Heritage Program, we had an instant connection; we talked about the Carnegie Museum and how Jack McCoy, our mutual friend, had jump-started his career, as well as mine. We had a few beers after work. Since then we remained good friends. Andy was a different person, some people may even say a strange guy, but with a big heart. I have visited with him a few times over the years with my wife and children, and he used to say, "These guys are some of my favorite people." He was one of our favorite people, too. I will remember Andy and will miss exchanging emails with him or having a beer.

I first met Andy Price at a Texas Herpetological Society meeting in the fall of 1994. He was the state herpetologist and I, being a naïve, young, graduate student, was the proverbial fly-on-the-wall bearing witness to a somewhat confrontational exchange initiated by several non-academic herpetologists about some rule or regulation about collecting long since forgotten. I remembered Andy as gruff, but holding his ground and arguing his point as much as helping the other side better elucidate theirs. He enjoyed giving that rough, stony persona as a first impression, but as my interactions with him increased when I moved to Austin for my Ph.D., I realized that was a bluff. He had a soft spot for students and for people genuinely interested in the organisms, but he had no patience for people using organisms to advance their politics or personal agendas. We became good friends, united by our passion for reptiles and amphibians (especially venomous snakes) and our mutual appreciation for herpetological literature.

To Andy, there was no gray literature, just literature he hadn't found yet. Several times at annual herpetology conferences, he'd be sitting in the hotel room at late hours of the night gleaning "obscure" feeding records while perusing several favorite search engines and databases. He was ideal as an editor for the *Catalogue of American Amphibians and Reptiles* series because of his obsession for finding everything published and persistence in vetting every citation listed in submitted catalog accounts. He was a true bibliophile and relished his opportunity to share his latest acquisitions with interested parties. He was also generous in making sure others could enjoy and use historical works. More than once, he saw a nearly destitute graduate student at a book dealer's table fondly gazing at a book important to the student's line of study, but priced well beyond their means. Andy would slip in later, buy that volume and then give it to the student, simply saying it was an important work and the student needed to have his own copy. He was very quiet with this generosity.

Following his cancer diagnosis, and with remarkable good humor, he persevered through many trials and tribulations during the ensuing treatment, which inevitably bought him six more years. Andy retired from Texas Parks and Wildlife in 2008 and was hired as a curatorial assistant at the Texas Natural History Collections at The University of Texas from 2009 to 2010. Andy clearly thrived in the collections setting and relished the interactions with the staff and students.

When the disease became ferocious in October 2011, we became much closer. I would visit him every other night following his hospitalization, and we talked for an hour or two about life. I took on the enabler role and smuggled in pints of chocolate chip ice cream. We talked turtles and toads, pushy relatives, and past relationships, academic and career choices, and the Pittsburgh Steelers. Even in the hospital, I would bring him his interlibrary loan requests, consisting of obscure archeological literature as he continued his search for the next missing citation for his project. He was determined that life should continue as uninterrupted as possible and that a return to a normal life was around the corner. I think of him often and I count our series of conversations over those last three months as some of the most meaningful interactions I've ever had with another human being.

I'll never be able to match Andy's dry, sardonic sense of humor, but his dogged pursuit of literature and his attention to detail as an editor are just two of the many things I've admired about him. His influence will live on as I continue to build my own library of reprints while at the same time reviewing literature cited sections with a critical eye for the erroneously cited page number.

I remember the first day I met Andy Price. He was the gruff, bearded, reclusive member of the Natural Heritage Program, with the office at the far corner of the room, and I was the fresh-faced young TPWD wildlife biologist on a mission to build bridges and "have everyone get along." Andy later told me he also remembered the day he met that naïve young addition to the program and decided that we would indeed eventually get along.

"Learning to get along" happened in the best way possible—in the dark woods of Bastrop State Park, where my pastel-clad friend allowed me to re-experience and relearn the joys of basic ecological research—through capturing, measuring, and marking hundreds of Houston Toads. Those evenings in the field might have kept both of us sane during a tumultuous period when our day-time duties were filled with endangered species controversy and stress.

Eventually I chose to step back from the controversy and work with outreach and education, launching a citizen science program called Texas Nature Trackers (TNT). Andy served as a resource and encourager to TNT as we began to recognize the particular value of citizen scientists in monitoring reptiles and amphibians. His efforts with Wendy Hodges on the status survey for the Texas Horned Lizard provided the inspiration for Texas Horned Lizard Watch. He organized a statewide meeting on amphibian decline in 1998 that led to the development of Texas Amphibian Watch. He also wrote the background sections for the original Texas Amphibian Watch, Texas Horned Lizard Watch, and Texas Box Turtle Survey monitoring materials and introduced potential volunteers to the joys of box turtle watching by recounting his own childhood experiences with the species.

Despite his own research load, Andy was always ready to share advice with us in his own wry manner. Even after his retirement from TPWD, Andy helped promote Texas Nature Trackers by inviting us to give guest presentations at Southwestern University.

Though infamous for his gruff demeanor, Andy had a compassionate heart—one that my family experienced first-hand in 2006 when my daughter was hospitalized following an automobile accident. Andy himself was just recovering from his first rounds of treatment for multiple myeloma, but wanted to come and sit with my daughter in ICU so that our family could be together for a meal. In his final days, facing his own time in the hospital once again, he told my daughter how happy he was for her recovery. As the two of them shared a moment that only two individuals who have faced eternity could understand, I was very glad that I had braved that corner office and its curmudgeon with the secret soft heart back in 1990.

Andy Price was a unique individual, with an opinion and expertise in all things herpetological. He did not like the political realities of wildlife conservation and was outspoken on his feelings. It was a great pleasure working with Andy on the *Amphibians and Reptiles of New Mexico*. He understood the systematics of the genus *Cnemidophorus* (now *Aspidoscelis*) better than most herpetologists, so who better to write a section on the lizards of his beloved state, an area to which he had longed to return. He was a careful and knowledgeable editor and his expertise resulted in numerous books and manuscripts that were better after his touch.

Cancer is tough, sometimes it wins the battle, thankfully not always! Andy fought a gallant fight and openly shared what he was going through. He had an extremely tenacious grasp on life; I am sure most individuals could not hang on as long as he did and I told him so often. Last time I saw Andy was in his precious New Mexico; my wife, Andy, and I each ordered a plate of enchiladas and talked about New Mexico food, herpetology, and the Gila Wilderness that he loved and where he spent numerous days hunting for Tassel-eared Squirrels. When Andy passed on, the field of herpetology lost a great guy and someone with so much more to contribute. I will miss him, and I think of him often.

CURRENT RESEARCH

The purpose of Current Research is to present brief summaries and citations for selected papers from journals other than those published by the American Society of Ichthyologists and Herpetologists, The Herpetologists' League, and the Society for the Study of Amphibians and Reptiles. Limited space prohibits comprehensive coverage of the literature, but an effort will be made to cover a variety of taxa and topics. To ensure that the coverage is as broad and current as possible, authors are invited to send reprints to the Current Research section editors, Beck Wehrle or Ben Lowe; e-mail addresses may be found on the inside front cover.

A listing of current contents of various herpetological journals and other publications is available online. Go to: http://www.herplit.com and click on "Current Herpetological Contents."

Molecular and Morphological Analyses Reveal Two New Neotropical Highland Vipers

Over the last decade, molecular studies have shed new light on Neotropical diversity within the family Viperidae. Vipers of the genus *Cerrophidion* occur in the high elevations of Central America. Recent work has winnowed this genus down to three species: a pair of species with small distributions in the Mexican states of Veracruz and Chiapas, respectively, and one species (*C. godmani*) discontinuously distributed from eastern Oaxaca through western Panamá. The authors of this study accumulated morphological and mitochondrial DNA sequence data for *Cerrophidion* specimens throughout their distribution and conducted molecular phylogenetic analyses to determine if there is cryptic diversity in this genus. These analyses demonstrated that *C. godmani* consists of at least three genetically divergent and geographically discrete clades: a northwestern clade occurring from Oaxaca through central Guatemala, a central clade in Honduras and El Salvador, and a southern clade in Costa Rica. These clades are as genetically distinct from each other as they are from the other two *Cerrophidion* species, supporting the authors' hypothesis that they represent undescribed species. In corroboration with previous studies of *C. godmani*, this study found no variation in hemipenial morphology and external morphological characters were found to exhibit a high degree of within-population morphological variation and an absence of strong differentiation between populations or regions. However, this and previous studies identified several morphological characters for which the recovered clades exhibit different mean values. The authors posit that the paucity of morphological divergence between regions, further obscured by high within-population variation, has prevented previous researchers from identifying cryptic diversity within this genus. The authors describe these three *C. godmani* clades as species (including a redefined *C. godmani*). This study enhances our understanding of Mesoamerican snake diversity and lays the framework for future studies that include analyses of morphological data explicitly testing hypotheses of morphological divergence and evolution, use of nuclear DNA data and recent molecular methods of species delimitation and species tree estimation, and additional sampling in areas where these snakes do occur (e.g., Chiapas, Panamá, southeastern Guatemala) and where they may occur (e.g., Nicaragua).

Jadin, R. C., J. H. Townsend, T. A. Castoe, and J. A. Campbell. 2012. Cryptic diversity in disjunct populations of Middle American montane pitvipers: a systematic reassessment of *Cerrophidion godmani*. Zoologica Scripta (*in press*) doi:10.1111/j.1463-6409.2012.00547.x.

Common Wall Lizards Shake a Leg to Discourage Predators

Behaviors that could function to discourage predator pursuit, such as stereotyped tail movements, dewlap protrusion, and foot waving, have been documented for representatives of several squamate families. Although many instances of predator-deterrent behavior have been proposed, relatively few studies have sought to explicitly test this hypothesis against alternative hypotheses (e.g., courtship, intraspecific aggression, thermoregulation). Members of the family Lacertidae have long been known to engage in various forms of foot-waving (including a particular elliptical motion of the foreleg sometimes observed in lizards approached by humans), but whether this behavior ever functions in deterring predators has not been established. The authors of this paper conducted field studies of Common Wall Lizards (*Podarcis muralis*) aimed at determining if foot waving in this species conforms to a pursuit-deterrent behavior. Researchers approached *P. muralis* and observed lizard responses (fleeing, moving to another location, foot waving, or some combination of these), noting the "predator" distance that initiated the behavior. Statistical tests were performed to determine if the findings conformed to the following expectations of foot waving being a pursuit-deterrent behavior: 1) adult males no more likely to engage in foot waving than any other category; 2) the foot waved is most frequently the one closest to the threat; and 3) the farther away the threat is, the more likely the lizard is to engage in foot waving. Of 484 lizard approaches, 22.5% resulted in foot shaking. The lizards used the leg closest to the researcher significantly more often than the other, and the probability of the leg shaking rather than moving was positively correlated with distance. The distance at which adult males responded to approach did not differ from adult females; however, at any given response distance adult males were more likely to move than leg wave (perhaps because of their relatively conspicuous coloration). Finally, most observations of leg shaking occurred sufficiently far from conspecifics to rule out intraspecific signaling. Together, these findings provide support for this behavior functioning as a pursuit-deterrent. Future research should determine whether this type of foot shake is also used in situations other than interactions with potential predators.

Font, E., P. Carazo, G. Pérez i de Lanuza, and M. Kramer. 2012. Predator-elicited foot shakes in wall lizards (*Podarcis muralis*): evidence for a pursuit-deterrent function. Journal of Comparative Psychology 126:87–96.

Female Common Lizard Dispersal Patterns Coincident with Ventral Coloration

Populations exhibiting multiple life history strategies serve as windows into how multiple phenotypes can be maintained in the face of drift and selection. Recent work on Common Lizards (*Zootoca vivipara*) in southern France has shown that in this region, female ventral coloration is polymorphic (orange, yellow, and mixed) and moderately heritable. These belly colors are correlated with the way litter size, breeding success, and sex ratio vary with different environmental and social conditions, indicating that ventral colorations are tied to alternative life history strategies. Furthermore, it has been established that individual reproductive success is tied to the ratio of color morphs in the population, namely the frequency of yellow-bellied females has an inverse relationship with the average female reproductive success, with a disproportionately larger effect on mixed females. The authors of this paper conducted an experiment to determine if the distance newborn female lizards disperse within populations is correlated with their ventral coloration (and thus strategy). They were also interested in the overall population's female ventral color ratios, as it would be beneficial for young lizards to disperse farther if in a situation where their strategy is disadvantageous. In four isolated populations, two with high frequencies of orange and two with high frequencies of yellow, gravid females were collected in the early summer and allowed to give birth in captivity. The females and their offspring were marked and released in the late summer into populations were their belly color was in the minority. Surveys of the populations were conducted in the fall and spring. These procedures were repeated for three years; by the end of the experiment the prevailing ventral color in each population had become a minority constituent and vice versa. These experiments revealed that as frequency of yellow females increased, offspring of orange and mixed (but not yellow) females dispersed less. Furthermore, as the frequency of orange females increased, the offspring of yellow females increased their dispersal distance, with offspring of orange and mixed showing no change. When dispersing, juveniles moved into areas with lower female densities. Offspring of orange and mixed females dispersed to areas with a higher proportion of yellow females, and the former also found areas with a lower proportion of orange females; all other comparisons were not significant. This finding seem to be at odds with the fact that females with yellow ventral coloration have been shown to be more aggressive than other females; the authors suggest that if they are superior competitors, yellow females inhabit higher-quality areas, which are good areas for dispersing lizards to settle (especially since the areas to which juveniles are relocating have lower densities than their original point of release). This study sheds more light on an interesting system and paves the way for genetic and long-term demographic studies of these populations.

Most Widely-Distributed Amphibian Evaluated with Respect to Bergmann's Rule

Bergmann's Rule, which states that body size should increase with decreasing temperature (and therefore often increasing latitude or elevation), has long been accepted for endothermic groups. However, whether the rule applies to ectotherms has been a topic of heated debate, with numerous studies supporting and rejecting this theory for various reptile and amphibian groups. Recent studies of *Plethodon* salamanders have found an inverse Bergmann's pattern both within and between species, with the implication being that while thermoregulating ectotherms (animals that adjust body temperatures via behavior; e.g., frogs, turtles) may conform to Bergmann's Rule, thermoconformers may not. The authors of this paper studied the world's most widely distributed amphibian, *Salamandrella keyserlingii* (Hynobiidae), with the hopes of determining how life history and growth varied across the salamander's distribution, and in particular if it conformed to Bergmann's Rule. One population in Darhadyn, Mongolia (~51°N), was intensely studied through mark-recapture and skeletochronological (the study of patterns left by fluctuating bone growth activity to determine animal age) techniques to elucidate within-population size statistics (e.g., sex-specific size at metamorphosis, sexual maturity, and maximum size). These data were then compared with results from a similar study from Kushiro, Japan (~43°N) to identify potential latitudinal/temperature differences. Additionally, total length (TOL) and snout-vent length (SVL) maximum values were compared across 27 populations spanning 43° to 69°N. While Darhadyn males had a smaller SVL than their Kushiro counterparts, no significant differences were detected for females or metamorphs. Males and females did exhibit smaller a TOL in Darhadyn than in Kushiro. Both sexes showed a much older age at maturity at Darhadyn (~5 years) than in Kushiro (~2–3 years). These results alone support an inverse Bergmann's rule in this system. However, size data from across the distribution lead to a different conclusion. These data show that there is no correlation of SVL with temperature, latitude, or TOL. While TOL shows no significant linear relationship with either latitude or temperature, a "U" shaped polynomial equation shows a better fit to the data, with TOL decreasing from 8° to –7°C mean annual temperature and 43° to 57°N latitudes and increasing from –7° to –15°C and 57° to 69°N; no such polynomial relationship was seen for SVL. The authors suggest that this fits the converse of "Terentjev's Optimum Rule" (coined to describe some inverted U-shaped patterns of size variation across and environmental continuum, though no mechanism for this pattern has been proposed) rather than Bergmann's Rule. They further suggest that the U-shaped size distribution perhaps indicates that different factors may be operating throughout the distribution; for instance, below a certain temperature threshold, size might become a secondary determinant of persistence, and instead a size-independent characteristic such as freeze tolerance takes over as the primary determinant.

Complex Effects of Plant Material and Light Availability on Anuran Biomass Export

Numerous studies have investigated the effect of nutrient availability on stream biomass export in the form of arthropods to surrounding terrestrial habitats; however, fewer studies have looked at the effects of nutrient availability on biomass export in lentic systems, or biomass export attributable to amphibians. The authors of this study subjected water-filled cattle tanks to different plant material input treatments to determine the effects on amphibian biomass export. These tanks received varying amounts of sunlight, and either leaf litter, Prairie Cordgrass (a wetland plant serving as a proxy for within-system vegetation), or no additional plant material. These tanks were then seeded with larvae of Wood Frogs (*Rana sylvatica*), American Toads (*Bufo americanus*), or Southern Leopard Frogs (*Rana sphenocephala*) (depending on year) and monitored for metamorphs. Prior to metamorphosis, the tanks were evaluated for numerous variables, including four the authors identified *a priori* as potentially important for amphibian biomass export: dissolved oxygen, net primary productivity (NPP; determined by monitoring daily dissolved oxygen fluctuations), predators (dragonfly larvae), and interspecific competitors (treefrog larvae). Upon metamorphosis, animals were weighed and released. ANOVAs and path analyses were performed to identify and visualize the importance of these variables for frog biomass export. Availability of sunlight was found to have a strong, positive effect on NPP and competitor density. While biomass export appeared to consistently decline with increased NPP across all species and plant material treatments, no species' biomass export was found to be significantly affected by NPP alone. *R. sylvatica* and *B. americanus* showed a significant NPP by plant material treatment interaction, with significant decreases in export as NPP increased in the cordgrass and no-input treatments. Biomass export in *R. sphenocephala* was found to be significantly affected by treatment (but not NPP or NPP x treatment interaction), with the highest export seen in the leaf litter treatments and the lowest in the no-input treatments. In the path analyses, depending on the treatment and species, the four variables identified above combined to explain between 18% and 89% of the biomass export. These analyses revealed that NPP consistently had a strong, generally negative effect on anuran biomass export. Considering that NPP is indicative of algal densities, the authors suggest this negative effect of NPP on amphibian biomass export means that algae may not be as important for larval anurans as traditionally assumed. This conclusion is supported by the general finding that NPP had little effect on biomass export in the leaf litter treatments (indicating that the tadpoles were eating the leaves and associated microbes). The authors concede that this relationship may also be due to other effects of increased sunlight (which drives NPP) such as increased temperatures (which were monitored but not analyzed due to the non-independence of temperature and dissolved oxygen content).

Diverse Male Reproductive Contribution Despite Female-Skewed Sex Ratios in Sea Turtles

Marine turtles all exhibit temperature-dependent sex determination (TSD), with females developing at higher incubation temperatures; this could lead to dangerously skewed sex ratios with anticipated climate change. As these species are generally imperiled worldwide due, among other factors, to the loss of egg-laying habitat and to adult mortality from fishing industry by-catch, the added impact of climate change could be too much for these species to overcome. To investigate potential consequences of a skewed sex ratio in marine turtles, the authors of this paper studied Green Sea Turtles (*Chelonia mydas*) in the Mediterranean Sea, where the female offspring have been documented to greatly outnumber male offspring. In 2008, tissue samples were taken at Alagadi beach, northern Cyprus, from 20 of 22 females who laid clutches that year and from 15 to 23 hatchlings from each successful female. All samples were genotyped for 14 microsatellite loci; these data were used to assign parentage and sibship to all of the offspring using parentage analysis software. While no molecular data on potential sires was collected, the nearly complete female and clutch sampling for the region allows maternal genetic contribution to be accounted for, leaving the remainder of the offspring's genetic signature to fathers. Finally, one adult male turtle was captured in the region, fitted with a satellite radio transmitter, released, and followed in order to shed light on male turtle movement patterns. Analyses of the hatching times revealed that the offspring were roughly 95% female. Despite this extreme observed sex ratio, the genotype analyses revealed that while some female turtles laid mixed paternal clutches, no male contributed to more than one clutch. Taking into consideration the number of females and clutches, 1.4 males reproduced for every one female. The satellite tracked male turtle revealed a possible explanation for this paradox. The turtle first swam north from the coast of Cyprus to Turkey; it then followed the coastline around the eastern edge of the Mediterranean Sea, ending along the Egyptian coast. This route passed in the vicinity of 58% of the Mediterranean *C. mydas* nesting grounds. The authors suggest that the breeding behavior of males may buffer the species from skewed sex ratios expected to result from increased regional temperatures.

Rampant Adhesive Toepad Gain and Loss in Gekkota

Once thought to be a derived character uniting crown geckos, recent molecular analyses of Gekkota have shown that adhesive

toepads likely have been acquired and lost independently multiple times in this group. To more rigorously test this hypothesis, the authors of this paper performed multilocus phylogenetic analyses using a dataset comprising 244 gecko species (107 of 118 genera) and about 4,100 base pairs of sequence data per species. Using the preferred phylogenetic tree (or a set of trees from the posterior distribution of trees), data on adhesive toepad condition were used to perform ancestral state reconstruction analyses aimed at determining where in the phylogeny toepad condition has changed. Finally, in addition to an unconstrained ancestral state reconstruction, analyses were performed wherein (1) the speciation rates and/or extinction rates were constrained to be the same in both padded and padless lineages, and/or the two rates of switching between conditions were constrained to be the same, and (2) either the acquisition or loss of the trait were constrained to a single instance. The fit of these different constraint models were then compared to the unconstrained models via Akaike information criterion (AIC) scores. These analyses supported previous studies in failing to recover toepad-bearing geckos as monophyletic. Ancestral state reconstruction found evidence for roughly 20 character state changes, with about eleven gains and nine losses. Models forcing converse parameters to share the same value did not significantly reduce the fit of models to the data; indeed, the best-fitting models were not the unconstrained model, but instead the models that constrained the rates of switching from one state to the other to be the same, and constrained either the extinction rates or the speciation rates to be the same. The two models that constrained either toepad gain or loss to a single event fared very poorly relative to all other models. While net diversification rates appeared to be higher in the padded lineages, this difference was not statistically significant, implying that the presence of adhesive toepads alone does not explain broad patterns of diversification among geckos. The authors provide detailed accounts of unambiguous toepad gains and losses, chart the repeated evolution of the "leaf toed" character state, and discuss the anatomical underpinnings of adhesive toepads and how they might have allowed this derived character state to have evolved repeatedly in this clade.

Reconciling *Desmognathus* with Dollo's Law

Since the discovery that salamanders in the genus *Desmognathus* ("dusky salamanders") with free-living aquatic larvae are highly nested within Plethodontidae and that, therefore, a biphasic life history is very likely a derived condition in these salamanders, researchers have tried to reconcile this finding with Dollo's Law, which states that once lost, complex traits do not reappear, and therefore must be re-evolved *de novo*. Radical changes to the hyobranchial apparatus occur in biphasic salamanders during metamorphosis, as the need for gill support and suction feeding is replaced with terrestrial feeding and the need for tongue protrusion. If the ability to form a functional larval hyobranchial apparatus is lost, it would need to be re-evolved for a direct-developing salamander to acquire a free-living larva. Researchers studying direct-developing relatives of metamorphosing *Desmognathus* have found some developmental differences, namely the absence of several features associated with a free-living larval existence. In particular, these studies failed to find evidence of the fourth epibranchial cartilage, part of the hyobranchial apparatus present in biphasic *Desmognathus*, the early-diverging plethodontid *Hemidactylium*, and non-plethodontid salamanders. To more thoroughly investigate this question, the authors of this paper conducted a more detailed study of the development of *Plethodon cinereus*, a direct developing relative of *Desmognathus* that likely exhibits a developmental sequence similar to that of the most recent common ancestor of the two genera. They generated sectioned specimens and/or cleared and stained whole mounts for eleven developmental stages and scrutinized them for the appearance and development of hyobranchial features. The authors found a fleeting appearance of the fourth epibranchial during the early part of developmental stage 20. They posit that this vestigial feature was elaborated upon in the evolutionary branch leading to biphasic *Desmognathus*. Furthermore, they observed the larval hyobranchial apparatus initially forming and subsequently being replaced by the adult version, a developmental process previously thought to be restricted to metamorphosing plethodontids (as a study of the distantly related direct-developing *Bolitoglossa subpalmata* did not find evidence of this). While some features characteristic of biphasic plethodontids appear to have evolved independently in *Desmognathus* (such as the palatopterygoid bone), it seems that others were preserved in the larval stages of direct-developing species.

First Discovery of Fossil Vertebrates Engaged in Reproduction

It is exceedingly rare for a fossil to encapsulate behavior; however, such fossils have been found that formed while the animal was engaged in combat, feeding, and rearing offspring. The authors of this paper describe a series of turtle fossils representing the first discovery of vertebrates to have died and been fossilized in the act of reproduction. Over the last three decades, nine pairs of *Allaeochelys crassesculpta* (Carettochelyidae) have been unearthed in the Messel Pit Fossil Site south of Frankfurt, Germany. The authors of this paper investigated these specimens for evidence of reproductive activity. They found that all the pairs consisted of one male and one female, seven of the nine were fossilized with the pair's posterior regions in contact, and two of the males had their tails wrapped beneath the females. This site boasts the only complete fossil carettochelyid skeletons ever found. During examinations of these, the authors discovered that the females possessed a hinged plastron which is not present in the species' sole living relative, *Carettochelys insculpta*, but is present in some non-carettochelyid turtle species and is hypothesized to aid in egg-laying. The authors posit that as these

turtles likely respire through their scale-free skin (as their sister family Trionychidae does), they may have succumbed to a deoxygenation of the water (perhaps caused by a release of volcanic gas), which killed them during the act of reproduction.

Cane Toad Larvae Readily Consumed By Australian Insects

Invasive populations of exotic species face different predators than populations in their native ranges, and to some degree their success can often be attributed to a release from predation pressures. Cane toads (*Rhinella marina* [*Bufo marinus*]) found Australia to be bereft of predatory vertebrates capable of tolerating the toad's toxins. However, little research has focused on potential invertebrate predators and the impacts they may have. The authors of this paper investigated the degree to which three Australian invertebrate species (one predaceous water beetle and two belostomatid bugs) eat *R. marina* eggs and tadpoles. First, representatives of the species were fed *R. marina* eggs and tadpoles to verify that they could eat them and survive. Individual insects were then offered two choices: *R. marina* eggs, hatchlings, or tadpoles, and an alternative (e.g., tadpoles of one of three native species, *R. marina* of a different developmental stage, small native fish). In a separate experiment aimed at testing the efficiency of these insect predators, individuals were placed in containers with a known number of *R. marina* tadpoles and six days later the surviving tadpoles were counted. An additional, similar test was performed with the diving beetle wherein tadpoles of two additional frog species were also present, and vegetation was included to add complexity to the environment. Finally, *R. marina* tadpole swimming performance was evaluated with respect to four native anuran species. Appropriate control treatments and replications were included for all experiments. These experiments revealed that indeed these three insects will consume immature *R. marina* and in doing so, experienced no significant increase in mortality. Differences in developmental stage preference were found, including the two belostomatid species preferring different tadpole stages, and only the beetle eating eggs. In the preference experiments, the beetle and smaller bug both preferred *R. marina* over any other offered prey items, while the larger bug preferred *R. marina* to fish but preferred tadpoles of two native frog species to toad tadpoles. The presence of all three insect predators significantly reduced survivorship of *R. marina* tadpoles, with the greatest impact observed in beetle treatments. In the complex environment experiment, *R. marina* experienced a fourfold increase in mortality when beetles were present; the effect on two native tadpoles present was negligible. In the swimming performance trials, *R. marina* were significantly slower than the four native species examined; toad tadpoles are much smaller and this factor largely explains the difference in speed. The authors suggest that the smaller size, slower speed, or some combination thereof could explain the insect species' preference for *R. marina* tadpoles, and that the lack of a coevolutionary history with Australia's native arthropod predators may leave *R. marina* particularly vulnerable. The authors suggest future work should investigate the population dynamics of insect predators in areas of *R. marina* invasion.

Diagnostic Classification of Connective Tissue Encapsulating Transmitters and Data Acquisition Units: Evidence for Not Modifying a Classic Surgical Implantation Method

Since the introduction of Reinert and Cundall's (1982) procedure for the surgical implantation of radio transmitters, their paper has been cited extensively and has become the standard surgical implantation procedure for snakes (Table 1). However, a recent suggestion (Bryant et al. 2010) for modifying Reinert and Cundall's (1982) procedure requires an additional step for suturing and anchoring a transmitter to a rib and its pre- and post-intercostal musculature. Such modification (in our opinion) seems more invasive than necessary and might be avoided by simply revisiting the surgical implantation method and transmitter preparation described in Reinert and Cundall (1982) and Reinert (1992).

The suggested methodological modification stems from observations of implanted transmitters and other data acquisition units (e.g., iButtons®) migrating within (or being expulsed from) the body cavity of snakes (Bryant et al. 2010; Pearson and Shine 2002). However, numerous collaborations and extensive work with a diversity of snake taxa (Table 1), using Reinert and Cundall's (1982) surgical protocol, have not typically presented the observations and concerns outlined in Bryant et al. (2010). Here, we revisit an important, but apparently overlooked, procedural step presented in Reinert and Cundall (1982) and Reinert (1992) that aids in stimulating connective tissue encapsulation, thus circumventing the migration or expulsion of implants.

Connective Tissue Encapsulation.—It is our conviction, from extensive observations, that the "1:1 mixture of paraffin and beeswax" used in potting transmitters (see Reinert and Cundall 1982; Reinert 1992) causes a foreign body reaction—an important immunological response that encapsulates a foreign body that cannot otherwise be digested by histiocytes (macrophages) (Anderson et al. 2008). Transmitter potting as suggested by Reinert and Cundall (1982) is an important procedural step that may be ignored, particularly by researchers who do not build and pot their own transmitters. However, Reinert (1992) made a further recommendation that "Even if you purchase completely assembled and potted units from a manufacturer, I suggest that you dip them in a 1:1 beeswax/paraffin mixture." Commercially available transmitters are often encased with multiple layers of biologically inert compounds (e.g., silicones and Teflon) that prevent tissue reactions associated with immunological response. For example, surgical implantation of Holohil transmitters (Holohil Systems, Ltd., Ontario, Canada) in Cottonmouths (*Agkistrodon piscivorous*) by WIL (Roth 2005a,b) produced no tissue encapsulations until transmitters were later coated with a 1:1 paraffin-beeswax mixture.

Although this paraffin-beeswax coating was first suggested "to produce a non-abrasive, indigestible, tissue inert final package" (Reinert 1992), the adherence to this recommended procedure (Reinert and Cundall 1982; Reinert 1992) by investigators may have produced the same fortunate and successful outcomes of transmitter encapsulation that we now acknowledge. Herein we present histological images and provide a diagnostic classification of the tissues encapsulating iButton® temperature loggers resulting from immunological response and the foreign body reaction.

Tissue Sampling, Histology and Microtechniques.—We sampled tissues from four individual snakes (two Southern Copperheads, *Agkistrodon contortrix*, and two Western Cottonmouths, *A. piscivorous*) that were implanted with iButton® temperature loggers following the surgical procedure described for transmitters by Reinert and Cundall (1982). All temperature loggers were coated with a 1:1 paraffin-beeswax admixture prior to implantation. After 56 days, the implants were removed using the same surgical procedure. A sample of the tissue sheath encapsulating each iButton® (Fig. 1) was biopsied and fixed in AFA (alcohol, formalin, and acetic acid). We used standard histological procedures (Hamason 1962) where tissues remained in AFA solution for 24 h after collection. Dehydration was initiated in 70% ethanol and continued at 1 h intervals through a graded series of ethanol washes, ending in two final washes with 100% ethanol.

Tissues were cleared to near transparency with three 1 h washes in histological grade xylene, permeated for 1 h in a 50:50 solution of melted paraffin and xylene, and transferred to melted paraffin to remove xylene residuum. We then cased tissues in paraffin molds utilizing standard blocking procedures. Tissues were sectioned at 7 µm thickness, floated in a warm water bath and mounted to slides with albumin adhesive (egg albumen and glycerol). Prepared tissue sections were stained in hematoxylin and counterstained in eosin. Stained sections were then dehydrated with ethanol through an ascending graded series, cleared in xylene and permanently mounted with Damar balsam mounting media.

Examination of prepared tissue sections was conducted using an Olympus B-Max 41 compound microscope with 10x, 40x, and 100x universal planapochromatic objectives with either bright field or phase contrast condensers. Digital photographs of microscopic images were taken using an Olympus DP-12 digital camera.

Tissue Diagnosis.—The encapsulating tissue examined was dominated by irregular and densely packed collagen fibers (Fig. 2). Two cell types were readily apparent within all planes of this encapsulating tissue. The small elongate cells responsible for secreting the collagen matrix are fibroblasts (Fig. 2; black arrows). Histiocytes (Fig. 2; white arrows) are responsible for initiating an immune response associated with engulfing foreign debris (Cline 1994; Leeson and Leeson 1979).

The Importance of the Paraffin-Beeswax Mixture in Potting Transmitters.—Anderson et al. (2008) outlined the inflammatory response following material implantation. Paraffin and beeswax, unlike inert coatings on some commercially potted transmitters, initiate the foreign body response. This is an additional response within a series of immune reactions normal to wound healing, specifically occurring in the persistence of foreign particles or bodies that may otherwise hinder healing. Foreign body reactions are ultimately characterized by the encapsulation of a foreign body that cannot otherwise be phaged by immune cells. However, several steps must occur before the process of encapsulation begins. Monocytes, once signaled by chemoattraction, leave the vascular system and enter connective tissue and become histiocytes. These histiocytes migrate by chemoattractive signals to the site of implantation (Anderson et al. 2008; Leeson and Leeson 1979) and begin adhering and interacting with the foreign body with the assistance of plasma and extracellular matrix proteins. Fusion of histiocytes results from their inability to phage the foreign body and become foreign-body giant cells which remain intimate with the surface of the foreign body (Anderson et al. 2008; Dee et al. 2002; MacLauchlan et al. 2009). During this foreign body reaction, residuum histiocytes initiate the remodeling of the extracellular matrix by secreting proteins that modulate fibrosis. Fibrosis (rapid production of the fibrous capsule) and the persistence of histiocytes are readily observed in Fig. 2A–B. Anderson et al. (2008) and MacLauchlan et al. (2009) discuss the benefits of effectively isolating the foreign body from host tissue. These benefits are easily realized in research efforts incorporating the surgical implantation of transmitters and data acquisition units where such units are encapsulated.

A More Recent and Related Implantation Issue.—Lentini et al. (2011) conducted histopathic and bacteriologic examinations of tissues resulting from the surgical implantation of transmitters into the intracoelomic space of Eastern Massasauga Rattlesnakes (*Sistrurus catenatus catenatus*). These transmitters were potted in a silicone coating, and the procedure of Reinert and Cundall (1982) was not followed reportedly because of prior difficulties with the technique (Lentini et al. 2011). After 14 months of implantation, transmitters were surgically examined *in situ* for tissue encapsulation, surgically removed and then swabbed for aerobic and anaerobic bacterial culture. The encapsulating tissues were also removed for histopathic examination. Both histopathic and bacteriologic findings were graded on a scale of 1 to 4 based on adhesion properties of the capsule and bacteria cultures, respectively. Lentini et al. (2011) concluded that these transmitters caused extensive irritation to internal tissues resulting in high rates of inflammation and infection. However, we question the findings presented in Lentini et al. (2011) as their histological images (i.e., figure 2, Plates A–D) are inconsistent with tissue growth associated with a foreign body reaction. Lentini et al. (2011) ascertained that the histology of the capsules was characterized by loose vascular connective tissue and simple cuboidal epithelium with eosinophilic cytoplasm. However, connective tissue types are diagnosed by differentiating the proportions of cells, fibers, and amorphous ground substance (Leeson and Leeson 1979).

Figure 2A in Lentini et al. (2011) clearly illustrates simple cuboidal epithelium. However, encapsulating connective tissue of a foreign body will not contain cuboidal cells which are specialized for secretion or absorption and thus predominate in glandular tissue. It is our conjecture that the glandular tissue presented in figure 2A by Lentini et al. (2011) may have been mistakenly isolated from the surrounding lumen or subcutaneous tissue (hypodermis) rather than the connective tissue encapsulation.

We further question the histological image described in their figure 2B as "loose connective tissue with scattered lymphoplasmacytic cells, histiocytes, and rare heterophils" with "a focal small granuloma characterized by low numbers with a few histiocytes surrounding refractile foreign material" (Lentini et al. 2011). Despite the poor magnification of figure 2B (Lentini et al. 2011), it appears that this tissue is not characteristic of loose (areolar) connective tissue. Our assessment is that figure 2B (Lentini et al. 2011) actually shows dense irregular connective tissue with an imbedded neurovascular bundle containing venules, arterioles (containing red blood cells), and a nerve fascicle characteristic of subcutaneous tissue. Venules and arterioles are readily identified by endothelial cells surrounding their lumens and residuum red blood cells, suggesting that the authors have mistakenly isolated subcutaneous tissue rather than the connective tissue encapsulating the foreign body. Finally, the low quality and poor magnification of figures 2C and 2D (Lentini et al. 2011) render them unsuitable for detailed cellular level diagnostics.

Contrary to the results presented by Lentini et al. (2011), Tucunduva et al. (2001) diagnosed the cells associated from the inflammatory processes following the subcutaneous implantation of cotton suture threads and circular coverslips in *Boa constrictor*. Their results are consistent with typical foreign body reactions and concur with our diagnostics presented here. The presence of histiocytes, foreign body giant cells, and various lymphatic cells are present in a matrix of dense irregular connective tissue surrounding the foreign body.

Recommendations.—Although many commercially prepared transmitters are potted in a supposedly inert coating, we recommend that researchers follow the procedures outline by Reinert and Cundall's (1982) surgical method which includes coating or potting the transmitter for implantation with a 1:1 paraffin-beeswax mixture. This ultimately allows for recognition and encapsulation of the transmitter following an immune response

FIG. 1. Image of an iButton® encapsulated by a thin sheath of connective tissue after 56 days of implantation in *Agkistrodon piscivorous*. Thicker encapsulations are seen with longer periods of implantation.

and foreign body reaction. Such tissue reactions "wall-off" the transmitter, preventing its migration within the body cavity. HKR examined a dead Pine Snake (*Pituophis melanoleucus*) that was implanted by a veterinarian with a transmitter that did not have a paraffin-beeswax coating. The snake had reportedly been sedentary and lethargic for several months prior to its death. It was found that the transmitter and antenna had migrated anteriorly and subsequently lodged in the snake's lung resulting in extensive irritation, inflammation, and eventual death.

The paraffin-beeswax coating described by Reinert and Cundall (1982) is a non-abrasive but organic compound, thus allowing it to be recognized by the body's immune responses. As a result, it is rapidly coated with connective tissue forming an anchored pouch within the peritoneum that may be used for repeated replacement of transmitters (Fig. 3). We recommend that all transmitters be dipped in a paraffin-beeswax mixture prior to implantation regardless of their original coating.

Although some snakes (e.g., Pythonidae) may have the ability to absorb and expel transmitters through the gut cavity (Pearson and Shine 2002) as documented in fishes (e.g., Rainbow Trout, *Oncorhynchus mykiss*), we assert that this problem in snakes and even fish may be circumvented with paraffin-beeswax coated implants (Helm and Tyus 1992). We also note that implants positioned in the "peritoneal" (Reinert and Cundall 1982) cavity are surrounded by the parietal peritoneum of the body wall and the visceral peritoneum of the surrounding internal abdominal organs. This placement of implants within the peritoneal membrane and posterior to the stomach and other internal organs may help circumvent the potential expulsion of transmitters through the feeding induced proliferation and dramatic up-regulation of the lumen demonstrated in Pythonidae (e.g., Secor and Diamond 2000).

We and our colleagues have collectively performed Reinert and Cundall's (1982) surgical procedure on hundreds of colubrid and viperid snakes over 40 years of combined research without the problems (e.g., high incidence of infection rates and transmitter expulsion) described by Bryant et al. (2010) and Lentini et al. (2011). HKR has removed transmitters from Timber

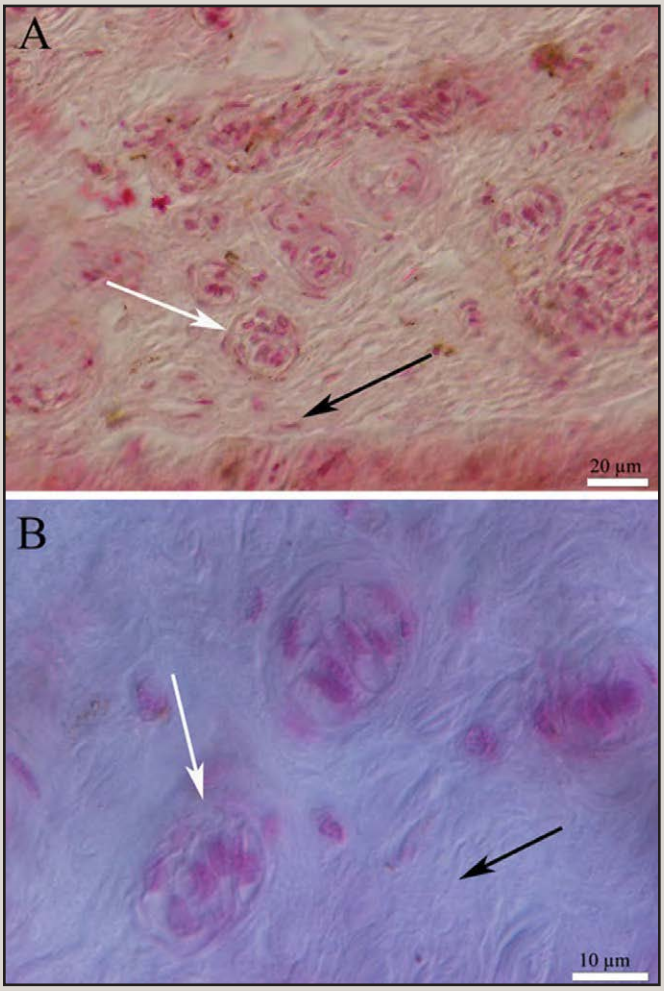

FIG. 2. Photomicrograph of encapsulating tissue taken from *Agkistrodon piscivorous* exhibiting the classic signs of a foreign body reaction. The dense irregular connective tissue consisting of tightly packed, irregularly woven collagen fibers is shown (A). Histiocytes in early stages of aggregation (white arrow) and small elongate fibrocytes (black arrow) are readily detected at 20x magnification. Histiocytes at 100x magnification (white arrow) and the tightly woven arrangement of collagen fibers (black arrows) indicate granular connective tissue allowing for the successful encapsulation of the foreign body within the peritoneal cavity (B).

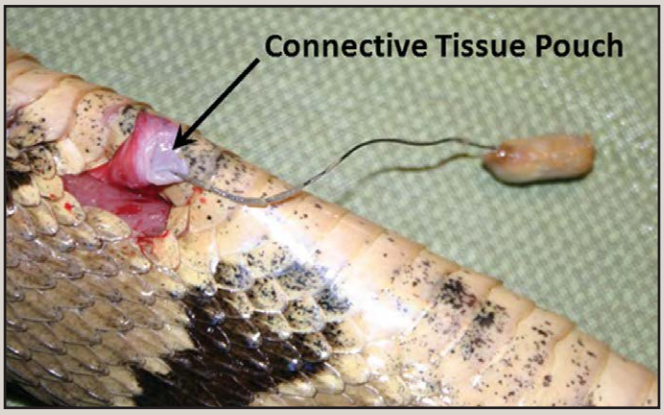

FIG. 3. A thick encapsulation and anchored pouch of connective tissue associated with a twelve-month implantation of a transmitter within the peritoneum of *Crotalus horridus*.

TABLE 1. Partial alphabetical listing of snake species studied by researchers that cite the procedure described by Reinert and Cundall (1982) for surgically implanting radio-transmitters or data acquisition units.

Rattlesnakes (*Crotalus horridus*) that have been encapsulated within anchored pouches of connective tissue in the peritoneal cavity for more than 12 years without migration, expulsion, inflammation, or infection (Fig. 3). Recently, we have performed this surgical procedure (Reinert and Cundall 1982) on more than 40 *Boa constrictor* (closely related to the Pythonidae). Similar to *Crotalus horridus*, these boas have shown no transmitter migration, expulsion, or detrimental inflammation, but rather connective tissue encapsulation, rapid healing, and long-term retention (up to 5 years). The utility of this surgical procedure has been employed and proven in a diversity of taxa (Table 1) including the Pacific Lamprey, *Lampetra tridentate* (Vella et al. 1999). Additionally, the procedure can be practiced both under laboratory and field conditions (Hardy and Greene 2000) and is widely accepted by institutional animal and care and use committees (Anderson and Talcott 2006). Consequently, we maintain that simple adherence to the original transmitter preparation recommendations and surgical procedure described by Reinert and Cundall (1982) will prove to be successful in most applications.

"Cobra de Capello," Plate VII from James Forbes' *Oriental Memoirs: Selected and Abridged from a Series of Familiar Letters written during Seventeen Years' Residence in India: including Observations on Parts of Africa and South America, and a Narrative of Occurrences in Four India Voyages*, published in four volumes by T. Bensley, London (1813). A second edition was published in two volumes by Richard Bentley in 1834. The hand-colored illustration (24 x 30.2 cm) depicts a *Naja naja* that was drawn in 1770 based on a snake captured in Bombay (Mumbai) after it had bitten a woman at the market. Forbes (1749–1819) traveled to India in 1765 in the employment of the British East India Company and remained there until 1784, compiling 152 volumes (52,000 pages) of notes on the flora, fauna, architecture, religions, and indigenous cultures of India. When he returned to England, he assembled these notes into his *Oriental Memoirs* masterwork. The books contain 93 plates drawn by Forbes, of which 28 are hand-colored. In addition to "Cobra," three other plates depict herpetological subjects, but only the cobra is depicted by itself. Plate VIII is a sketch of a musician playing his flute to a swaying cobra as spectators look on (drawn in 1772); Plate XXV includes a *Chamaeleo zeylanicus* on a Neva Tree branch (1768 or 1772); Plate XC includes a "Malabar Spotted Frog" (*Hylarana malabarica*) on the ground with a Black and White Kingfisher in an aquatic plant above it (1784). The latter two plates also are hand colored. References to amphibians and reptiles are few in the text except for a detailed account of the effects of *Naja* snakebite on dogs. The book is still considered an exceptional source of information on India's west coast in the late 18th Century, and its colored plates are highly valued. The plates can be viewed at the British Library Online Gallery (http://www.bl.uk/onlinegallery/index.html).

Negative Oral Responses of a Non-Canid Mammalian Predator (Bobcat, *Lynx rufus*; Felidae) to Ocular-sinus Blood-squirting of Texas and Regal Horned Lizards, *Phrynosoma cornutum* and *Phrynosoma solare*

Horned lizards (*Phrynosoma* spp.) are noted for their commitment to restriction of movements and apparent reliance on crypticity for avoiding detection by predators (Cooper and Sherbrooke 2010a, b, c, 2012; Sherbrooke and Montanucci 1988), as well as a diversity of defensive responses to varied categories of predators once detected (Sherbrooke 1981, 2003). An ocular-sinus blood-pressure system regulated by two pairs of sphincter muscles surrounding major cranial veins is found in all lepidosaurs (Bruner 1907; Heath 1966). Apparently from this system horned lizards have evolved a unique antipredator defense of squirting systemic blood from their tear ducts into the mouths of selected predators that may find the chemical-containing blood distasteful (Middendorf and Sherbrooke 1992; Middendorf et al. 2001; Sherbrooke and Mason 2005; Sherbrooke and Middendorf 2001, 2004).

Reports of predators eliciting blood-squirting by horned lizards have been limited to members of the canid family (Dogs, *Canis familiaris*; Coyotes, *Canis latrans*; and Kit Foxes, *Vulpes macrotis*) and to humans (*Homo sapiens*, low frequency) (Middendorf and Sherbrooke 1992; Sherbrooke and Middendorf 2001, 2004; Hodges 2004; Sherbrooke and Mason 2005). Oral receptors for blood-borne chemicals eliciting strong negative behavioral responses in canids (Sherbrooke and Mason 2005) are apparently lacking in humans (Middendorf and Sherbrooke 1992, N = 4 humans; WCS experienced subsequent personal observations of a lingering very-mild, barely-perceptible, acrid after-taste lasting 30–45 min following tasting of freshly-squirted blood of *Phrynosoma cornutum*, N = 10+ lizards). This narrow taxonomic category (canids) of potential predators known to elicit the behavior persists in spite of testing of a broad variety of horned lizard species and a diverse spectrum of known predators (that either dismember or swallow prey whole). These include Greater Roadrunners (*Geococcys californianus*), Southern Grasshopper Mice (*Onychomys torridus*), Long-nosed Leopard Lizards (*Gambelia wizlizenii*), Western Diamondback Rattlesnakes (*Crotalus atrox*), and Coachwhips and Sonoran Whipsnakes (*Masticophis flagellum* and *M. bilineatus*) (Sherbrooke 1990, 1991, 2008; Middendorf and Sherbrooke 1992; Sherbrooke and Middendorf 2001, 2004; Sherbrooke and Mason 2005; Sherbrooke and May 2008). Middendorf and Sherbrooke (1992) suggested that some non-canid medium-sized mammalian carnivores might elicit blood squirting by horned lizards and respond negatively to the blood-borne chemicals, and thus be deterred from further attack.

We carried out predator-prey trial encounters with two species of horned lizards (*Phrynosoma cornutum* and *P. solare*) known to squirt blood defensively at canid predators and not at some other predators. We asked, "Might a threat by a distinctly different mammalian predator of another family (Felidae), a Bobcat (*Lynx rufus*), induce these lizards to utilize a blood-squirting defense?" We hypothesize that blood squirting induced by a bobcat threat would suggest that the lizards categorize canids and bobcats similarly when electing to utilize this antipredator defense. In addition we asked, "Do bobcats respond to ocular-sinus blood-squirting by horned lizards with negative behaviors indicating that they have oral-cavity receptors capable of sensing chemical compounds in the lizards' blood that are distasteful to them (similar to canids)?"

Methods

Texas Horned Lizards (*Phrynosoma cornutum*; 3 males, 83, 87, 98 mm SVLs; Iguania: Phrynosomatidae) were road collected from Hidalgo Co., New Mexico, USA, on 21–24 May 2010 and fed crickets (*Acheta domesticus*) in captivity in Portal, Arizona (through 6 June; Southwestern Research Station), and crickets

plus some seed-harvester ants (*Pogonomyrmex rugosus*) in Tucson, Arizona, prior to testing with bobcats at the Forever Wild Animal Rehabilitation Center in Tucson on 22 June 2010. Trials were video recorded (Sony 12x FullHD 1080), photographed, and notes were written following each trial.

Analysis of video recordings involved focusing on defensive behaviors of the lizards: run, freeze, raise horns (Sherbrooke 1987), dorsal shield (a behavior widely used with other predators; Sherbrooke 1990, 1991, 2003, 2008; Sherbrooke and May 2008), tail raising (Middendorf and Sherbrooke 1992; Sherbrooke and Mason 2005; Sherbrooke and Middendorf 2004), flipping on back (Sherbrooke and May 2008), swelling of eyelids (as a precursor to blood-squirting; Middendorf and Sherbrooke 1992), and blood squirting or emitting blood from around eyelids. Also, the video analysis focused on bobcat investigative behaviors of lizards and negative reactions of the bobcats to squirted blood (or skin-surface adhering or pooling ocular-sinus blood exuded around the lizard's eyes). These reactions by bobcats included retreating, lateral head-shaking, tongue extrusion and licking, lip licking, briefly rolling onto one body side on the ground, and salivation.

The three Texas Horned Lizards were separately introduced between 0920–1100 h into a cage (chain-link wire; 3.7 x 7.6 m, 3.7 and 3.85 m split height; with hardware cloth mesh wire along the lower 1 m) containing a surrogate mother and six sibling bobcats, 2–3 months old. On 27 June three recently collected (21 and 25 June, Pima Co., Arizona) Regal Horned Lizards (*P. solare;* males, 89, 90, 96 mm SVLs) were introduced into the same enclosure (0910–1005 h; 32°C) with the seven bobcats tested the previous week and responses were similarly recorded.

Trial times varied with bobcat and lizard behaviors. Due to cage arrangements some actions were difficult to interpret with certainty during video analysis by WCS. The adult female bobcat did not engage the horned lizards.

In 2011 six adult *P. solare* (males, 69, 72, 84, 87, 89, 97 mm SVLs) were collected southwest of Tucson, Pima Co., Arizona. Lizards were generously fed local seed-harvester ants (*Pogonomyrmex rugosus*), with some additional feedings of domestic crickets. The single female fifteen-month-old bobcat used in trials was housed at the Southwest Wildlife Conservation Center in Scottsdale, Arizona. This bobcat had become very tame, allowing handlers and filming crew to work within its 6 x 12 m, 3 m high chain-link cage (with hardware cloth mesh wire along the lower 1 m). The bobcat's trial activities and video recording (recorded by AM; Red Epic M video camera; for real time 30 frames/sec and slow-motion 120 frames/sec; not continuous throughout the trials; video reviewed by WCS) were largely confined to a single focused location. Trials on 23 June 2011 were in the late afternoon following the heat of day, 1648–1730 h. The durations of the three trials were approximately 12, 18, and 25 min. On 24 June five trials were held in the early morning, 0720–0900 h and lasted 10, 19, 40, 5, and 12 min. These trials included one lizard used on 23 June, and one used twice on 24 June; thus a total of six Regal Horned Lizards were exposed to the bobcat.

Results

Bobcats and Phrynosoma cornutum *(2010).*—In all three trials (2010) with *Phrynosoma cornutum* and seven bobcats in a single cage there were nearly continuous behavioral interactions between individual juvenile bobcats that often appeared to involve control (possession) of the lizard. Bobcat behaviors included pawing the lizard and picking it up in the mouth while emitting growling threats and lateral tail wagging. The lizard was held across its body (side to side) in the bobcat's mouth, usually from above, with the hindlegs, tail, forelegs, and head extending laterally to both sides, beyond the bobcat's jaws. The lizards were never bitten, chewed, or picked up by the head or limbs. A lizard-controlling bobcat often, but not always, caused other bobcats to retreat and then put the lizard down to be immediately held in place with a forepaw, talons not clearly extended. The lizard was often sniffed around the head and sometimes released and chased and recaptured under a forepaw. Extensive use of the forepaws in manipulating ("playing with") the lizard was noted. This tactile manipulation occasionally led to release of additional eye-sinus blood without a squirt projecting a stream of blood.

In the first trial (25 min) there was no swelling of eyelids or blood squirting by the lizard in response to the bobcat's activities. One bobcat controlled the lizard, carrying it around in its jaws or pinning it to the ground with a paw. During persistent sniffing of the forehead of the lizard, the lizard raised its horns on two occasions and it briefly raised its tail to a vertical position twice, for a second each time. No dorsal shield defensive postures were seen.

In the second trial (15 min) the lizard squirted blood within the first minute of the encounter resulting in several minor tongue-extention licks by the bobcat that was carrying it and had put it down. When the bobcat picked up the lizard in its jaws again the lizard squirted, leaving a streak of blood across fur on the lower left jaw of the bobcat. The lack of immediate reaction by the bobcat suggests that the squirted blood did not enter the bobcat's mouth. Areas around both of the lizard's eyes were already coated with blood prior to subsequent pawing by a second bobcat. The quantity of blood on the lizard's head appeared to increase during this second-bobcat's pawing, which may have involved a small squirt or oozing of blood from near the eyelids, which remained closed. The bobcat licked blood on the lizard's head and then moved away while exhibiting a series of tongue extending and licking actions, and shaking its head laterally. While walking away from the lizard it widely opened and closed its jaws and extended its tongue (about once per second) and flexed it in multiple directions while turning its head from side to side. This lasted for one minute following which the bobcat lay down and rolled onto one side and then back onto its other side before returning to a four-footed stance. A fresh patch of blood appeared on the side of the lizard's back (not an injury; probably due to a fresh blood-squirt not observed) and on the ground when the same bobcat returned to pawing the lizard. Investigation of the blood (licking and/or smelling) on the lizard's head by another bobcat then led to it retreating and exhibiting similar, but not as exaggerated, lateral head-shaking and rolling onto its two sides. There were no tail raised, dorsal shield, or horns raised displays by this lizard.

In the third trial (20 min) a group of three or four bobcats began pawing the lizard immediately after it was placed in the cage. The lizard responded with swollen eyelids, raised horns, raised tail, and blood around both eyes. One bobcat licked its own lips during this encounter. Bobcats continued to sniff the lizard's head and tentatively pawed it repeatedly for over five minutes before the actions of a single bobcat elicited a blood squirt from the lizard's right eye. Subsequently a bobcat licked blood from the lizard's head and this bobcat briefly shook its head and licked its open mouth. Both lizard eye areas were now blood-coated and the same bobcat returned to the lizard and during further

FIG. 1. A bobcat, reacting to ocular-sinus blood from a Regal Horned Lizard (*Phrynosoma solare*) contacting its oral tissues, exhibits multiple mouth opening-and-closings, eye closing, lip retraction, and contorted and varied tongue-extensions, all accompanied by vigorous lateral head-shaking.

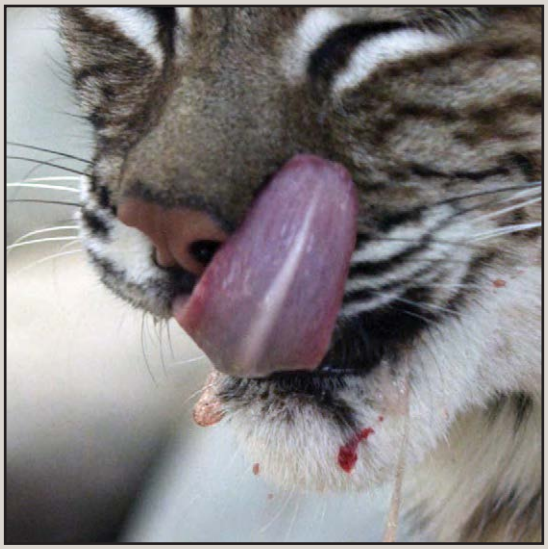

FIG. 2. Bobcat reacting to ocular-sinus blood from a Regal Horned Lizard (*Phrynosoma solare*) contacting its oral tissue surfaces. Note that the bobcat's eyes are closed, its tongue is extended in licking actions, there is a spot of horned lizard squirted-blood on its left chin hairs, and saliva strands are dangling from its lower fore-jaw on both right and left sides of its mouth.

pawing and sniffing again shook its head laterally. As the bobcats repeatedly pawed the lizard and briefly walked away before returning, the lizard either relaxed its swollen eyelids, or on recontact, it reenacted the swollen-eye state, at the same time raising its horns (tilting its chin downward) and lifting its tail. No bobcat picked up the lizard in its mouth in this final trial. No dorsal shield displays were observed.

Blood squirting was observed in trials 2 and 3, but not in trial 1. Negative reactions of three bobcats to the squirted blood occurred in trial 2, and with at least one bobcat in trial 3 (possibly a bobcat that also reacted in trial 2).

Bobcats and Phrynosoma solare *(2010).*—In all three trials the bobcats' behaviors seen in essentially continuous handling of Regal Horned Lizards were similar to those noted earlier with *P. cornutum*, including repeated pawing and chasing, paw holding, tapping of the lizards' heads with fore-paws, and frequent sniffing of lizards' heads. But the carrying of lizards crosswise through the bobcat's mouth while growling only occurred during the first trial. Lizards failed to raise their tails, raise horns, inflate their bodies, or display a dorsal shield defensively. Lizards usually maintained eyelids open between repeated paw patting/striking of the head and body throughout the trials. Only two very brief instances of eyelid swelling were seen late in trials (trials 1 and 3). An apparently small blood-squirt, 1.5 min into the third trial (duration 15 mins), resulted in a single lateral head-shake and nose-lick response by the bobcat. In trials 1 (duration 15 mins) and 2 (duration 10 mins) there were no indications of blood squirting by the lizards, in spite of continual manipulation.

Bobcat and Phrynosoma solare *(2011).*— During trials with this single somewhat-older juvenile bobcat, lizards were not picked up and carried around in the bobcat's mouth as was seen in 2010 with *P. cornutum* and *P. solare* when multiple bobcats were present. But similarly, the lizards were frequently "played with," pawed by the bobcat. Investigations by the bobcat of the lizards were intermittent and frequently involved sniffing and licking, particularly of the head.

On 23 July all three lizards exhibited swollen eyelids in response to the bobcat's investigation of the lizard and two of three lizards squirted blood during their trials. Following the first trial, in which no blood-squirting occurred, during the second trial the lizard squirted blood from its right eye. This resulted in the bobcat exhibiting multiple bouts of rapid lateral head-shaking with tongue extrusions, apparently trying to clear its mouth of the blood-borne chemical irritants. Late in the third trial the lizard was placed (by KS) on the bobcat's side after it was lying down. Initially the bobcat exhibited no interest in the lizard, but then the bobcat reached back with its jaws and grabbed the lizard by its horns and gently tossed it off its back to the ground. During this procedure the lizard reacted by squirting blood from both eyes. As the bobcat revisited and licked the lizard's head (now covered by a small increasing pool of blood), the bobcat reacted with violent bouts of lateral head-shaking (3 cycles/sec maximum) accompanied by tongue extrusions and contortions (Figs. 1 and 2). Within minutes, copious amounts of salivary secretion resulted in drooling from both sides of the bobcat's mouth (Figs. 3 and 4). This viscous saliva hung and dangled from the bobcat's jaws, swinging with the bobcat's head motions, while a fluid drop accumulated at its lowest point. This fluid exhibited pinkish coloration, suggesting the accumulation of lizard-squirted blood within the saliva and its expulsion from the bobcat's mouth (Fig. 4). The duration of these immediate responses was about 1 min.

During the five trials on the second day (24 July), no lizards squirted blood, but at least one exhibited swollen eyelids. As in the first trial on 23 July, without a blood squirting event the bobcat did not exhibit lateral head-shaking, tongue extrusion or salivation.

During all eight trials no *P. solare* exhibited a dorsal shield display, but four displayed horns raised and four raised their tails, both reactions during encounters with the bobcat. In two trials the bobcat grabbed the lizard's tail in its jaws and gently tossed it into the air, less than 50 cm above the ground and near the bobcat. In one of these encounters the tail-raise/tail-toss sequence was

FIG. 3. Bobcat continues to react to ocular-sinus blood from a Regal Horned Lizard (*Phrynosoma solare*) contacting its oral tissues. Following its initial responses, the bobcat continues licking while its eyes open and its extensive salivary response transports some of the lizard's squirted blood from its mouth cavity.

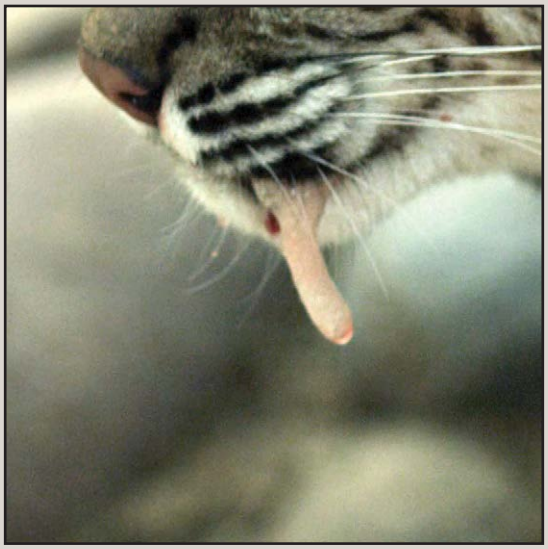

FIG. 4. Bobcat continues to react to ocular-sinus blood from a Regal Horned Lizard (*Phrynosoma solare*) contacting its oral tissues. At the tip of the strand of saliva dangling from the bobcat's mouth is watery-fluid with its pinkish color apparently illustrating contained lizard blood being expelled from the bobcat's mouth.

repeated three times within 1 min. In several trials the increase in eyelid bulging outward by the lizards was extensive, stage 3 or 3+ (Middendorf and Sherbrooke 1992) and sequentially repeated. Throughout the trials this pre-blood-squirting response was usually initiated as the bobcat lowered its face to close proximity to the horned lizard's head (often sniffing and sometimes licking). Eyelid swelling was reduced as the bobcat withdrew its head and then reinitiated on subsequent bobcat approach.

DISCUSSION

In earlier studies it has often proven difficult to determine if a species of horned lizard does or does not squirt blood ("non-blood squirting" species; Sherbrooke and Middendorf 2001) at a seemingly appropriate predator (dog bio-assays) or humans due to the difficulty in evaluating negative responses (Sherbrooke et al. 2004; Sherbrooke and Mendoza-Quijano 2005; Sherbrooke and Middendorf 2001; Sherbrooke and Rodriguez 2010). Nevertheless, a positive blood squirting response during exposure to canids by both *Phrynosoma cornutum* and *P. solare* is well established (Middendorf and Sherbrooke 1992; Sherbrooke and Mason 2005; Sherbrooke and Middendorf 2001, 2004). Blood squirting elicited by bobcats in the two species of horned lizard in this study, similar to canids, contrasts with numerous studies that resulted in a lack of a blood-squirting response to threats from other predators (Sherbrooke 1990, 1991, 2008; Middendorf and Sherbrooke 1992; Sherbrooke and Middendorf 2001, 2004; Sherbrooke and May 2008). These data support a hypothesis that the lizards select a single category, or somehow linked categories, of predator recognition in utilizing a blood-squirting defense.

Vital to the efficacy of a blood-squirting defense is a negative reaction by the recipient predator to chemical factors in the blood. Following five blood-squirting defenses by both *P. cornutum* and *P. solare* during trials with bobcats (in which blood entered the oral cavity) the felids demonstrated somewhat consistent negative responses. Quantities of squirted-blood reaching bobcat oral surfaces during any squirting or licking of blood were probably highly variable (Sherbrooke and Middendorf 2001). In all five cases the bobcat showed vigorous lateral head-shaking (of various duration), tongue extensions and retreat from the lizard. Following one blood-squirting defense by *P. solare* (2011) the bobcat showed excessive salivary production and extrusion of these fluids from the mouth, along with other vigorous responses. The consistency of negative gustatory behaviors following oral exposure to horned lizard squirted blood by at least five different bobcats demonstrates its potential utility as a defense against predatory threats by bobcats.

It is worth evaluating similarities and differences between reactions of bobcats to ocular-sinus blood-squirting by *Phrynosoma cornutum* and *P. solare* and reactions of kit foxes to *P. cornutum* blood squirting reported earlier (Sherbrooke and Middendorf 2004). Both kit fox and bobcat predators were juveniles with little or no pre-captivity experience in capture of live prey alone or with adults, thus their reactions were probably innate. In trials in which squirted blood entered into the predators' mouth both kit foxes and bobcats responded with lateral head shaking, mouth opening and closing sequences, closing eyes, and out-of-mouth tongue extensions (Sherbrooke and Middendorf 2004; this study). Tongue extrusions were less pronounced in kit foxes than in bobcats, and salivary drooling was not seen in kit foxes. Kit foxes did not roll onto a side, but in one case, where grass was available, the fox repeatedly laterally wiped its muzzle on the grass. Bobcats appeared to sniff the heads of lizards repeatedly, a behavior not consistently observed with kit foxes. The strong negative bobcat responses during licking of blood and their absence during bobcat sniffing of lizards' blood-coated heads suggest that, as in coyotes (Sherbrooke and Mason 2005), the sensory receptors detecting antipredator compounds in the lizard's blood are located in the oral cavity and the chemical agents are not volatile compounds detected, and reacted to negatively, via the olfactory system.

Middendorf and Sherbrooke (1992) suggested that vertical tail-raising, observed in Texas and Desert Horned Lizards (*P. cornutum* and *P. platyrhinos*) during trials with dogs (Middendorf and Sherbrooke 1992; Sherbrooke and Middendorf 2001) and in *P. cornutum* with coyotes (Sherbrooke and Mason 2005) and kit foxes (Sherbrooke and Middendorf 2004), attracts attention away from a horned lizard's head and may have survival value. Jaw grabbing of elevated tails resulted in the dog quickly lifting and tossing some lizards into the air, with subsequent difficulty in relocation. Vertical tail-raising was seen in two of three *P. cornutum* bobcat trials (2010), but was not seen in 2010 *P. solare* trials. But in 2011, with an isolated bobcat, Regal Horned Lizards raised their tails during some trials, and in several cases the bobcat responded by grasping the tail and tossing the lizard. Thus, the use of tail raising behavior (as a possible distractive defensive behavior), by *P. cornutum* and *P. solare*, was noted during threats by both bobcats and kit foxes. This tail-raising behavior is absent in encounters with a wide variety of other predators that are challenged during prey subjugation and ingestion events by their inability to dismember these lizards prior to ingestion (Sherbrooke 1990, 2003, 2008; Sherbrooke and May 2008). Thus, horned lizards may only utilize vertical tail-lifting, as with ocular-sinus blood squirting, with a certain category of mammalian carnivores capable of dismembering lizard prey. However, detailed studies are needed to confirm this hypothesis.

Many horned lizards utilize size and spinyness enhancing displays, dorsal-shield, or flipping onto their back, during attacks by predators that ingest their prey whole (Greater Roadrunners, whipsnakes, Long-nosed Leopard Lizards; Sherbrooke 1990, 2003, 2008; Sherbrooke and May 2008) or that are relatively small mammalian predators facing difficulties in dismembering larger horned lizards as prey (Southern Grasshopper Mice; Sherbrooke 1991). Size-enhancing behaviors have not been reported when horned lizards were attacked by canids, dogs or kit foxes (Middendorf and Sherbrooke 1992; Sherbrooke and Middendorf 2001, 2004), or coyotes (Sherbrooke and Mason 2005). This lack of observations suggests that horned lizards may preferentially utilize these defensive behaviors with categories of predators lacking prey-dismembering abilities. Canids and felids may not normally elicit this behavior because as large carnivores capable of dismembering prey the size of horned lizards, and larger, a dorsal shield display would be a relatively ineffective defense. A horns-raised display not only thwarts whole-prey ingestion but also enhances spiny armament that can inhibit mammalian exploration of prey with sensitive mouth-area tissues. Matching defensive behaviors to specific categories and threats, venomous and non-venomous predatory snakes, has been established with both species of horned lizards reported on in this study (Sherbrooke 2008; Sherbrooke and May 2008).

Here we present the first evidence of a non-canid mammalian predator, that occasionally takes lizards (Bobcat, *Lynx rufus*; Delibes et al. 1997, Hoffmeister 1986; including *Phrynosoma* sp., Delibes and Hiraldo 1987), eliciting blood-squirting by Texas and Regal Horned Lizards and responding negatively to the lizards' blood contacting oral receptors. This suggests a potential role for horned lizard blood-squirting as an antipredator defense against this felid, and (by implication) possibly other untested non-canid mammalian carnivores. Further efforts toward understanding the categorization by horned lizards of appropriate predators for employing this blood-squirting defense and the responses by a diversity of potential predators to the blood would be instructive in further evaluating its survival value.

Acknowledgments.—For video recording assistance at Forever Wild Animal Rehabilitation Center (2010) we thank volunteers Dixie Moore, Warren Forrey, and Grace Kolack. Scientific collecting permits for collecting horned lizards were issued (to WCS) by the Arizona Game and Fish Department (permit # SP 594729) and New Mexico Department of Game and Fish (permit #1149). Arizona Game and Fish Department permits for bobcats were issued to the Forever Wild Animal Rehabilitation Center (# MB834736) and to the Southwest Wildlife Conservation Center (#s SP690299 and SP695597). The American Museum of Natural History's IACUC approved the study. No animals were injured during the study. We thank Selah Hobbie Jr. for valuable assistance (2011) and G. A. Middendorf, III, for permission for WCS to review kit fox/Texas Horned Lizard videos from an earlier study (Sherbrooke and Middendorf 2004). A short video of a kit fox's response to Texas Horned Lizard blood squirting (Sherbrooke and Middendorf 2004) can be seen in "Where Did the Horny Toad Go?" — http://jarofgrasshoppers.com/. Video of the bobcat's responses to the blood-squirting by *P. solare* (2011) appears in a 2012 National Geographic TV series, "Untamed Americas." We note that our collaborative efforts simultaneously involved scientific investigation, animal rehabilitation, care and conservation education at Forever Wild Animal Rehabilitation Center and Southwest Wildlife Conservation Center, and production of an educational natural history documentary film by National Geographic Television.

A Novel Approach to Counting Geckos: *Phelsuma* Density in Mauritian Forests

Variation in the ability to detect individuals is a key issue when estimating and comparing the density of animals in different habitats over time (MacKenzie et al. 2002; Mazerolle et al. 2007; Pollock et al. 2002). One suitable methodology that estimates density, while accounting for detectability, is distance sampling through line and point count surveys (Buckland et al. 2001). Most reptile surveys that have utilized the Distance methodology have been conducted on terrestrial species along line transects (see the distance sampling bibliography: http://www.ruwpa.st-and.ac.uk/distancesamplingreferences/). During a line transect survey an observer moves along a transect and records the perpendicular distance of each detected individual from the center line. These distance measurements are used to model detectability from an absolute number of detections at zero distance (Buckland et al. 2001). However, the detection of small arboreal reptiles from ground-based surveys in tall canopy forest is expected to be low and likely to violate the key assumption that all objects along the center line are detected with certainty (Buckland et al. 2001). Failure to detect all individuals on the center line results in a negative bias of the abundance estimate (Anderson et al. 2001; Buckland et al. 2001). To enhance the detection of canopy-dwelling reptiles it would be preferential to bring the center line closer to the canopy, but in most cases this would not be practical for line transect surveys. Another well known survey method that employs distance sampling is the point count survey, where the observer remains at a single location and records the distance to detected individuals in the surrounding area (Buckland et al. 2001). While the assumption of absolute detection at zero distance still applies, detection from a stationary point is likely to be higher at zero distance as there will be greater search effort than at any one point along a transect line where the observer is moving. Another potential benefit of point count surveys of arboreal reptiles in tall canopy forest is that the observer can conduct the survey from a stationary elevated position closer to or within the canopy to enhance detection at the zero point. The purpose of this research was to investigate the feasibility of conducting point count surveys of arboreal geckos from elevated survey platforms within the native forests of Mauritius in the Indian Ocean.

Despite the extinction of five endemic reptile species, Mauritius still supports a rich diversity of reptiles (Arnold 1980; Cheke and Hume 2008). However, only five of the twelve described endemic and extant species can be found on mainland Mauritius; the others are now restricted to small offshore islands (Arnold 1980; Cheke and Hume 2008; Cole 2009). Four of the endemic species not restricted to the smaller islands are arboreal day geckos: *Phelsuma cepediana* is a widespread and relatively common gecko; *P. ornata* is found in low to mid-elevation dry forest; *P. guimbeaui* is restricted to fragments of lowland scrub and dry to mid-humid forest in the west and southwest; *P. rosagularis* is restricted to highland forests in the southwest and southeast (Austin et al. 2004; Cole 2009; Vinson 1976). The Black River Gorges National Park (BRGNP), situated in southwestern Mauritius, supports the most intact remnants of native forest cover and is the last location to support all four *Phelsuma* species (Fig. 1; Cole 2009; Page and d'Argent 1997; Vinson 1976).

Although the general distribution of these *Phelsuma* species is fairly well known, there are very little data on local densities and no means to compare *Phelsuma* density between different regions of forest, or to determine population trends in relation to habitat degradation or restoration. This is not only important for the conservation of the Mauritian *Phelsuma*, but also for the conservation of other threatened species, such as the Mauritius Kestrel (*Falco punctatus*) that feeds almost exclusively upon *Phelsuma* at certain times of the year and endemic plants that are known to be reliant upon *Phelsuma* for pollination and seed dispersion (Burgess et al. 2009; Fox et al. 1985; Hansen 2006; Hansen and Müller 2009; Jones 1985; Temple 1987).

Elevated point count surveys were conducted to determine the feasibility of obtaining relative abundance estimates of the *Phelsuma* species in the BRGNP and whether it differed significantly between regions. We also investigated the influence of cloud cover, wind strength, observer height above ground, and the start time of the survey on the detection probability of *Phelsuma*. We present our results and discuss the validity of using elevated point counts to offer suggestions for future monitoring.

Methods.—Point count surveys for *Phelsuma* were conducted from December 2009 to February 2010 at five regions within the BRGNP (Fig. 1). Surveys were conducted in relatively intact native forest, often within Conservation Management Areas (CMAs). Point count locations were randomly selected, but spaced at least 20 m apart from each other, as Mauritian *Phelsuma* are rarely detected at a distance of more than 10 m within forest habitats (see Results). Sixteen point count locations were selected within the Beloquet and Fixon CMAs at Bel Ombre, 23 locations within the Brise Fer CMA, 16 locations within Dr Vaughan's CMA and a recently weeded area of forest in Macchabée, 21 locations within the Morne Sèche CMA, and 11 locations within forest at Petites Gorge (Fig. 1).

Within each of the forested areas, trees were identified for point count surveys based primarily on their height, so that an observation point could be selected within the average canopy height and allow a 360º view of the surrounding tree trunks and canopy. Young tall trees growing between mature trees were preferred as they were straight, relatively narrow and did not have substantial branching, which made them easier to climb. The observer wore a climbing harness and a tape was wrapped around the trunk to provide a foothold. A second tape was also wrapped around the tree and clipped to the harness with a carabiner to prevent the observer from falling. Additional tapes were required to climb over tree branches. Once in the canopy the observer selected a sturdy branch that provided a good view of the surrounding trees and branches from which to conduct the point count. From extensive observations of *Phelsuma* behavior, the slow movement of an observer ascending a tree will only disturb geckos within the immediate vicinity of less than 2 m. However, if an observer has passed or remains motionless geckos will return to their original perch position or resume normal behavior within a short period of time. To account for potential disturbance and avoid underestimates of *Phelsuma* density, the observer waited immobile with eyes closed for a minimum of 10 minutes after arriving at the observation point. Directly after the immobile period the point count was conducted over the following 20 minutes. These time durations were selected following observations of *Phelsuma* behavior and the ability to thoroughly search the surrounding vegetation within a time period where climatic variables between the start and end of a survey would remain comparatively similar. At the start of each survey

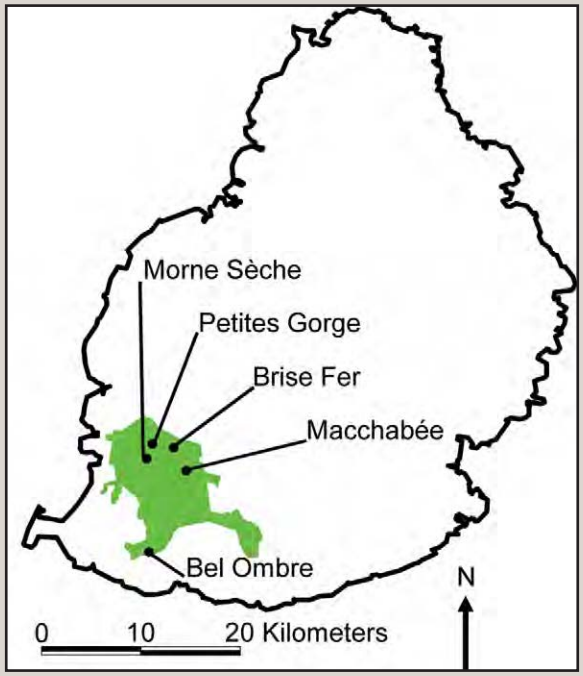

FIG. 1. Map of Mauritius and the Black River Gorges National Park (shaded green) with regions of native forest selected for point count surveys.

the time, percent cloud cover and wind strength (using the Beaufort scale) were recorded; observer height above ground was recorded after the point count. Point counts were not conducted during rain, as *Phelsuma* seek shelter and are hidden from view, and point count surveys occurred during hours of daylight between 0730 h and 1700 h when *Phelsuma* are known to be active. During each survey, any *Phelsuma* observed were recorded with the time of the observation and distance from observer. An extendable measuring tape was used for measuring distance to the nearest cm, and binoculars (Pentax XCF 8 x 40) were occasionally used to identify species. A minimum of 80 *Phelsuma* observations were recorded within each region. All observations and measurements at all of the sites were conducted by a single observer (T. Imlay).

Distance measurements from all point counts were imported into Distance 6.0 and region was assigned as the stratification layer to determine region-specific *Phelsuma* density and detection rate estimates (Thomas et al. 2010). Distance sampling utilizes a detection curve and abundance near the centerline to determine estimates of density (Buckland et al. 2001). The model assumes that all animals at a distance of zero are observed, animals are recorded at their initial position, and that distance measurements are precise (Buckland et al. 2001). Incomplete detection during the count can lead to underestimates of abundance, such that estimates should be treated as relative, rather than absolute (Rodda and Campbell 2002). Hectares were used as the unit of measure in Distance to create an index of relative density (geckos/ha). Point count surveys were conducted once from each of the selected trees within each region and were therefore assigned an effort value of one, unless the survey was cut short due to inclement weather. In these cases, effort was adjusted to reflect the observation time spent during the survey. At Morne Sèche, point counts conducted after 1500 h were excluded from the analysis as *Phelsuma* were not observed at this site after this time.

TABLE 1. Summary of region specific *Phelsuma* density estimates (D) with percent coefficient of variance (CV) and 95% confidence intervals (95% CI), where k is the number of point counts and n is number of observations pre- and post-truncation.

Region	k	n	D	CV	95% CI
Bel Ombre	16	88-81	753	20.5	499–1136
Brise Fer	23	80-72	607	19.7	412–896
Macchabée	16	82-70	576	26.0	338–981
Morne Sèche	21	80-74	627	18.5	435–904
Petites Gorge	11	80-76	1314	30.2	699–2472

TABLE 2. Probability values for Kolmogorov-Smirnov (KS) and Cramér-von Mises uniform (W-sq) and cosine (C-sq) weighted goodness-of-fit tests for distance data stratified by region and fitted to a half-normal model.

Region	KS	W-sq	C-sq
Bel Ombre	$p = 0.849$	$0.800 < p < 0.900$	$0.700 < p < 0.800$
Brise Fer	$p = 0.433$	$0.400 < p < 0.500$	$0.400 < p < 0.500$
Macchabée	$p = 0.850$	$0.600 < p < 0.700$	$0.600 < p < 0.700$
Morne Sèche	$p = 0.353$	$0.600 < p < 0.700$	$0.500 < p < 0.600$
Petites Gorge	$p = 0.705$	$0.500 < p = 0.600$	$0.500 < p < 0.600$

TABLE 3. Model selection results from the forward stepwise sequential addition of covariates on the half-normal detection model for all *Phelsuma* gecko distances stratified by region, where K is the number of parameters in the model and W is the Akaike weight.

Models	K	AIC	ΔAIC	W
Observation height and wind strength	15	5048.023	0.000	0.374
Observation height and start time	15	5048.067	0.044	0.366
Observation height, wind strength and start time	20	5049.030	1.007	0.226
Observation height	10	5053.025	5.002	0.031
Observation height and cloud cover	15	5058.134	10.111	0.002
Wind strength	10	5066.477	18.454	<0.001
Start time	10	5076.801	28.778	<0.001
Cloud cover	10	5078.625	30.602	<0.001
No covariates	5	5078.933	30.910	<0.001

Using the default settings, a detection curve was produced for each region to visually identify long right tails, which represent fewer gecko detections far from the observer. These outermost observations are difficult to model as they provide little information in estimating the density function at zero distance, which is the most critical part of the curve (Buckland et al. 2001). Long right tails were discarded by truncating the largest 10% of distances (Buckland et al. 2001). The multiple covariate distance sampling (MCDS) engine was used to include the covariates of time of day, percent cloud cover, wind strength and observer height above ground on all data stratified by region. Two models consisting of a key-function + series-expansion (half-normal + cosine and hazard-rate + simple polynomial) were fitted to the data. The most parsimonious model with the lowest Akaike Information Criterion (AIC) value, a compromise between the number of parameters and model fit, was selected. At each stage of the analyses default Kolmogorov-Smirnov and Cramér-von Mises uniform and cosine weighted tests were examined to assess the adequacy of the fitted models and to investigate any violations of the assumptions that underpin Distance methodology (Buckland et al. 2001; Thomas et al. 2010). Covariates were included one at a time and the one that gave the best model fit (the lowest AIC value) was selected, upon which the other covariates were sequentially added following a forward stepwise procedure until there was no further decrease in the AIC value (Thomas et al. 2009). If the difference between the AIC values (ΔAIC) was less than two units then the models were considered to be of equal suitability (Burnham and Anderson 2002).

Density estimates and detection probabilities with respective percent coefficient of variances and 95% confidence intervals were calculated for each region using the best-fitting model. An ANOVA followed by Tukey's *post hoc* comparisons was used to determine significant differences in the *Phelsuma* density between the five regions.

Results.—All four *Phelsuma* species were detected during the point count surveys. *Phelsuma cepediana* and *P. rosagularis* were detected at Bel Ombre, Brise Fer, and Macchabée; the former species was also detected with *P. guimbeaui* and *P. ornata* at Morne Sèche and Petites Gorge. A total of 410 individual *Phelsuma* were encountered during the 87 point count surveys conducted in the BRGNP, with at least 80 observations made within each region (Table 1).

Using the MCDS engine the half-normal key was selected as the best fitting model with a right truncation of the largest 10% of distances for each region. For each region the goodness-of -fit tests demonstrated good model fit in each case (Table 2). The stepwise inclusion of the covariates produced three suitable models whose ΔAIC values were less than two units and were of similar weight; these models included the covariates of observer height above ground, wind strength, and start time (Table 3). The detection of *Phelsuma* was enhanced at lower positions with the canopy at Bel Ombre and Brise Fer, at higher positions at Petites Gorge and observer height above ground had little influence on detection at Macchabée and Morne Sèche (Fig. 2). Overall *Phelsuma* detection was greater when the wind strength was low (Fig. 2). Detection was greater during the morning at Bel Ombre, Brise Fer and Morne Sèche and greater around midday and early afternoon at Macchabée and Petites Gorge (Fig. 2).

The model that included all three covariates was used to calculate the values of relative density for each region (Table 1). The relative density of *Phelsuma* was shown to differ significantly between the regions within the BRGNP ($F = 38.713$, $df = 4,82$, $p <$

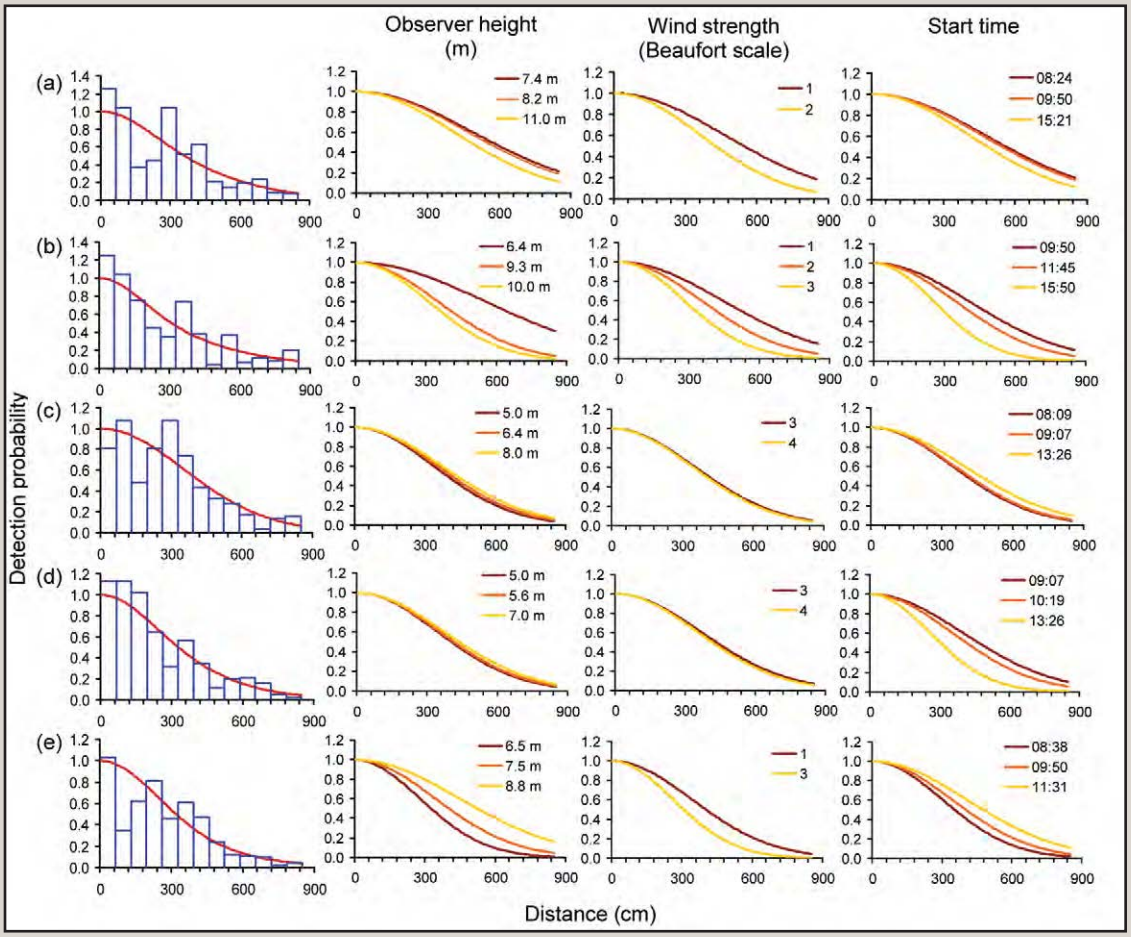

FIG. 2. Distance histograms with half-normal detection curves and the influence of the covariates on *Phelsuma* detection stratified by region: (a) Bel Ombre, (b) Brise Fer, (c) Macchabée, (d) Morne Sèche, and (e) Petites Gorge.

0.001). *Post hoc* comparisons demonstrated that relative *Phelsuma* density was similar between Brise Fer, Macchabée, Morne Sèche, but significantly greater at Bel Ombre and highest at Petites Gorge (Table 1).

Discussion.—Ground-based distance sampling surveys of arboreal lizards in tall canopy forest are unlikely to meet the key assumption that all individuals are detected on the zero point of observation with certainty (Buckland et al. 2001). Small lizards can easily go undetected at the zero point if they are hidden within tree cavities, or obscured by complex branching and dense foliage of the canopy several meters above the observer on the ground. Violation of this key assumption would lead to varying underestimates of density, such that comparisons between regions would produce spurious results. Conducting point count surveys at elevated positions are likely to enhance detection and reduce bias. The selection of tall young trees with few cavities and limited branching within the interconnecting canopy of neighboring trees permitted a clear view above and below the observation point, as well as the surrounding vegetation. The results from the goodness-of-fit tests demonstrate that there is little evidence to suggest that observations, particularly the zero point, were under- or over-dispersed. Nevertheless, in situations where there is some uncertainty in the ability to detect all individuals at the zero point, the double-observer method is recommended (Laake and Borchers 2004). In such cases the mark-recapture distance sampling (MRDS) engine can be used to relax the assumption that all objects are detected at the zero point (Thomas et al. 2010). Observer behavior on approach to the elevated observation point and the inclusion of the acclimation period are thought to have reduced responsive gecko movement permitting accurate measurements to be made of initial gecko locations during the survey period. This approach to counting geckos is considered to have met the other two key assumptions that objects do not move and measurements are accurate (Buckland et al. 2001).

The ability to detect *Phelsuma* was shown to vary in relation to the height of the observer within the canopy, wind strength, and start time. Both Bel Ombre and Brise Fer contained the most continuous canopy of native plant species with dense foliage and intertwining branches of all five regions. Lower observation sites in these forested areas provided a better view of the surrounding canopy. Petites Gorge contained the densest understory of invasive plant species and therefore, higher observation sites provided a better view of the surrounding vegetation. Sun penetration through the canopy at Bel Ombre, Brise Fer, and Morne Séche occurred earlier in the morning than Macchabée and Petites Gorge, providing excellent basking locations on tree trunks and branches. Dense understory vegetation at Macchabée and Petites Gorge limited the number of basking locations, and Macchabée received less direct sunlight early in the morning due to the westerly aspect of the gorge. The aspect of the region in the gorges also influenced gecko presence at the

northerly facing Morne Sèche which received very little daylight after 1500 h. Increasing wind strength resulted in the greater movement of vegetation within the canopy and this movement reduced gecko detectability. Wind strength may also be related to gecko activity, as during strong winds geckos tend to retreat to refuge sites. Regional and seasonal variation of other climatic variables, food availability and the presence of competitors and predators are also likely to influence *Phelsuma* activity and their use of refugia. The unavailability of individuals for detection can lead to a bias in the estimation of density (Rodda and Campbell 2002; Smolensky and Fitzgerald 2010). Variables that influence *Phelsuma* activity and thus detection must be accounted for and not differ substantially between regions and periods of time for direct comparisons of relative density. We recommend that surveys for *Phelsuma* within canopy forest are conducted on calm days when there is little wind, no rain and soon after sunlight first penetrates the canopy, when gecko activity and detection appears optimal. We also propose that an initial acclimation period of ten minutes is applied to account for disturbance related to reaching the observation point and tall young trees are selected to conduct point counts from a height where a suitable view of the surrounding trees and branches in the canopy is gained.

The four species of *Phelsuma* on mainland Mauritius are roughly the same size and color, with an average total length of 10–14 cm (Cole 2009). However, the detection rate of similar gecko species can vary greatly (see Rodda and Campbell 2002). Moreover, Harmon et al. (2007) demonstrated that in sympatry the Mauritian *Phelsuma* species compete for space and cause shifts in microhabitat use as reflected in perch height and type. These shifts are likely to alter species-specific detection rates under different species combinations in different habitat types. Further research is therefore required to determine the detection rates of each *Phelsuma* species in the presence and absence of congeners.

From this study we can tentatively suggest that Petites Gorge contained the highest density of geckos despite containing areas of relatively degraded forest in comparison to other sites (Page and d'Argent 1997). *Phelsuma ornata* was the most common species observed at Petites Gorge, which is dominated by boulders and rocky outcrops, a habitat feature known to support a high density of *P. ornata* on offshore islands (N. Cole, unpubl. data).

Elevated point count surveys appear to be an effective method for monitoring *Phelsuma* populations in tall canopy forest to determine their geographical distribution and documenting potential changes in their regional density in relation to habitat degradation or restoration. However, further work is required to determine species-specific variation in detection and what affects their activity to ensure surveys are conducted under appropriate conditions to remove potential bias. Elevated point counts may also be an effective method for monitoring other arboreal reptiles in tall canopy forest.

Acknowledgments.—This project would not have been successful without the knowledge and support of many people. In particular, we thank Andrew Skinner, Vikash Tatayah, Nicolas Zuel, Asha Poonyth, the staff at Camp and Bel Ombre field stations, and office staff of the Mauritian Wildlife Foundation. We thank the National Parks and Conservation Service (Mauritius) for support to the Mauritius Kestrel project. We also thank Stuart Newson, Richard Young, and two anonymous reviewers for their constructive suggestions. A stipend for the Canada's New Noah training program was provided by Wildlife Preservation Canada for Tara Imlay.

The Ecology of the Mink Frog, *Lithobates septentrionalis*, in the Adirondack Park, New York, with Notes on Conducting Experimental Research

The Mink Frog (*Lithobates septentrionalis*) is a cold-adapted amphibian widely distributed in Canada, but with limited distribution in the U.S (Gibbs et al. 2007; Hedeen 1986; Moore 1952). This largely aquatic amphibian has its southern distributional limit at the highest latitude of any North American anuran, with evidence that more southern populations became extinct in the past century (J. Gibbs, pers. comm.). Its occurrence is linked to cold, well-oxygenated wetland breeding sites (Hedeen 1986), and as temperatures continue to increase, there is evidence that climate change has the potential to impact extant southern populations, such as the ones in the Adirondack Park (AP), New York State (Gibbs et al. 2007; Popescu and Gibbs 2009).

Despite the likely threat to this species, little research has been conducted and the species is receiving scant management attention in the southern part of its range. This lack of attention may be related to its cryptic nature: 1) it calls late in the night and is unlikely to be heard during regular anuran call surveys, which are often conducted during the early hours of the evening (Bevier et al. 2004; Bevier et al. 2006; Popescu and Gibbs 2009); and 2) eggs masses quickly sink to the bottom of the water column. It also resembles the more widespread Green Frog, *Lithobates clamitans*. The net result is that Mink Frogs can easily go undetected if present. This was confirmed by Popescu and Gibbs (2009), who investigated the effects of land cover, disturbance, and historic climate on pond occupancy in the AP and surroundings. Two important aspects that emerged from the study were the association of *L. septentrionalis* with beaver impounded wetlands and the potential effects of climate change on future distributions in the AP. However, at the time of model development, no information existed relating changes in water temperature to growth and survival of aquatic life-history stages. This information is particularly relevant as the largely aquatic Mink Frog is known to be sensitive to water temperature, with previous studies suggesting that these conditions may determine patterns of occurrence (Hedeen 1986; Moore 1952).

In 2011 we conducted research combining field surveys and experimental habitat manipulations with the goal of understanding the potential implications of climate warming on Mink Frog ecology and future distribution. One of the most useful products we derived from this study was a greater understanding of the ecology of this species. This information is of direct relevance to those wishing to conduct further research with an organism that may well be one of the most threatened species in the United States in regards to climate change.

Methods

This study was conducted in the Adirondack Park in New York State (44.052470°N, 74.401623°W). This ~6-million acre upland region comprises the largest protected area in the contiguous United States. Our field studies focused on 73 wetlands, including both palustrine and lacustrine systems. These wetlands were selected to span a broad elevational (202–711 m) and latitudinal gradient (44.025293°N to 44.65734°N), with the goal of incorporating a range of climactic conditions.

Surveys were conducted from 28 June to 17 August 2011. Field technicians used canoes to make visual observations of calling behavior at a subset of five wetlands, and capture animals for experimental research. Wetlands were visited at night between 2200 and 0400 h, with observations being conducted over a minimum of a 2-h period. Each wetland was visited a minimum of four times during the survey period. Wetlands were also visited during the day on a sporadic basis during the survey period. Male frogs were almost always located from their calling, whereas female frogs were found through systematic sweeps across the wetland using canoes. Early attempts to capture animals using nets were relatively unsuccessful, whereas hand-capturing using a stealthy approach in the canoe was found to be far more effective. All animals captured were identified to species (using calls, odor, and the presence of mottles running down the length of the rear legs), and sexed using a combination of tympanum size (larger than the eye = male) and calling (Gibbs et al. 2007). The snout to vent length (SVL) was also measured by allowing animals to stretch along a plastic ruler while holding the rear leg.

In addition to the calling behavior assessed both in the field, we established breeding choruses in 3785-liter cattle tanks (~3 m diameter and 1 m deep). Although this aspect of the study was primarily for the purpose of obtaining eggs, it also allowed us to further evaluate calling. Cattle tanks had been previously filled with untreated water, with 100 liters of partially decomposed leaf-litter (~75% deciduous, 25% coniferous) added to each tank. We also placed a few lily pads and small branches in each tank to mimic natural conditions. We then placed ~10 Mink Frogs into each tank (approximately equal males and females). All of the frogs in a single tank were collected from the same wetland. Observations of calling males in cattle tanks were made anecdotally before looking for egg masses at night. Animals were not fed in tanks due to the abundance of natural food, and were released back to the point of capture within a week.

To assess oviposition behavior and egg mass characteristics, we looked for eggs in the field. We also placed pairs of animals (both in amplexus and prior to amplexus) in 53-liter plastic containers in the lab. These containers were filled halfway with lake water with a stick placed to encourage oviposition. Animals were left for a maximum of three days in these containers and were not fed during this time. Additionally, we made observations of any egg masses deposited in cattle tanks. To assess the characteristics of larvae we made observations of animals in the 53-liter containers and in cattle tanks.

Results

Calling Behavior.—Mink Frogs were heard calling throughout the study period and prior to the start of nocturnal surveying at a few sites. Calling was primarily nocturnal, although active choruses were heard on a few occasions throughout the day prior to the beginning of the survey period (early to mid June). A few individuals were also heard calling sporadically during the day in the survey period, but this represented a noticeable reduction in day-time calling compared to earlier in the season. Males were observed calling both while floating on the water's surface and from on lily pads (*Nymphaea odorata* and *Nuphar microphyllum*), with the latter calling behavior more prevalent in wetlands with high densities of lilies. When calling from lilies, males were partially in the water (front legs on the leaf, hind legs free). We did observe males sitting entirely on lily pads, but no calling was seen during these occasions. Males were typically spaced at least 2 m apart, whereas males would call in closer proximity in cattle tanks (typically at least 0.5 m apart). The location of breeding choruses was clearly related to the location of floating vegetation, specifically lily pads. In wetlands entirely dominated by lily pads, Mink Frogs appeared to prefer to call away from the edges of the wetland. In wetlands where lily pads were not common/present, Mink Frogs were typically less aggregated (often with over 10 m between animals), with one or two males calling from each submerged object such as a fallen tree nearer the shoreline. In one of our wetlands, both Green Frogs, *L. clamitans*, and American Bullfrog, *L. catesbeianus*, were also calling at the same time as the focal species. This beaver-created site was shallow (< 2 m deep) and dominated by lily pads across much of the water's surface. We observed clear spatial segregation among these species, however, with Green Frogs calling from the wetland margins and Bullfrogs from an area of emergent vegetation away from the Mink Frog chorus. In the early part of the season (June and early July), female Mink Frog were hard to locate, and were typically found floating in the water around the edge of the breeding chorus. Later in July and August, female Mink Frogs were often found intermixed with males.

Amplexus and adult size.—Amplexing pairs were rarely observed in the wild (a single pair was located in amplexus, out of the many hundreds of animals observed in breeding choruses). Amplexus could be readily stimulated by placing males and females in small (~10 liter) containers; however, many of these amplexing pairs did not lay eggs (see notes on oviposition below). When comparing the SVL of Mink Frogs captured in the field, we found males to be significantly larger than females (mean SVL [mm] ± Std. Dev.: Males [N = 47] 53.1 ± 3.6; females [N = 52] 46.9 ± 10.7; two-tailed *t*-test, $P < 0.001$). When comparing the SVL of Mink Frogs observed in amplexus, however (including animals that amplexed in the laboratory), we found males to be slightly smaller than females (males [N = 3] 54 ± 1.7; females [N = 6] 58.5 ± 6.74).

Oviposition.—Oviposition was observed in both the wild and under experimental conditions. Two egg masses were located during nocturnal surveys at a single site, Black Pond. Identification of these egg masses to species was facilitated by comparison with egg masses deposited under laboratory conditions. The first of these clutches was located on 28 July. Although these eggs had hatched, early-stage larvae were still associated with the egg mass suggesting that it had been laid within the week prior to discovery. The second egg mass was found on 10 August and did not contain any larvae. Both clutches were found in water that was ~1.5 m deep. The first clutch was attached to a slim branch of a submerged tree, approximately 70 cm below the surface of the water. The second clutch was at a similar depth in the water column, attached to the stem of a yellow pond lily (*Nuphar* sp.). Four egg masses were deposited under experimental conditions. The first two of these clutches were both laid on 7 July 2011 in 53-liter plastic containers filled approximately two-thirds full with pond water, with the remaining clutches laid in cattle-tanks. In the case of the clutches laid in cattle tanks, one clutch was observed attached to the stem of a floating lily pad (i.e., on the surface). The second clutch was not detected until after the tadpoles had hatched.

Time to hatching.—Egg masses laid in the 53-liter containers (water temperature 19.0°C) hatched within four days of being deposited. Initially, larvae remained motionless on the bottom of the container, with the first mobility observed eight days after hatching. The larvae in cattle tanks remained largely motionless during the day unless physically disturbed, but were observed to be active at night (observations conducted using flashlights).

Discussion

Our results support earlier findings on the general ecology of Mink Frogs. Specifically, we found Mink Frogs to be nocturnal breeders, with breeding aggregations closely associated with floating vegetation (Bevier et al. 2004; Bevier et al. 2006; Hedeen 1971; Leclair and Laurin 1996; Popescu and Gibbs 2009). We also found egg masses to be associated with submerged vegetation and to hatch rapidly. Beyond confirming existing information, however, we were also able to expand our knowledge of the focal species. Based on our results, Mink Frog breeding ecology differs from that of explosive breeders such as the Wood Frog, *Lithobates sylvaticus* (Gibbs et al. 2007). The explosive breeding strategy is portrayed as overwhelming potential predators through high number of breeding adults, eggs, and larvae concentrated in space and time such that predators can have little effect on population success. Mink Frogs, conversely, may "underwhelm"

predators, with a prolonged breeding season during which eggs and larvae are widely dispersed in wetlands and thus likely hard to find, making the cost of predation not worth the effort. The oviposition strategy of Mink Frogs also differs from the sympatric Green Frogs and American Bullfrogs, both of which deposit floating rafts of eggs on the water's surface (Gibbs et al. 2007).

We can offer two explanations for the fact that male Mink Frogs captured in the field were larger than females, whereas females were larger than males when considering amplexing animals only. The first is that juvenile males were misidentified as females in the field. We did observe juvenile animals during the course of this study; these animals were clearly much smaller than any of the animals associated with breeding choruses and occupied different habitat to calling animals (open pond margins during the day). None of these smaller animals was observed during nocturnal call surveys. We were also readily able to sex male animals associated with choruses during surveys (using clear differences in tympanum size and calling). The animals identified as females began entering the chorus some time after it had started (initially we only captured males); it is hard to think of a reason for a cadre of immature males to enter the chorus at the same time as reproductively active females, particularly if they themselves are not yet able to breed. The second explanation is that all of the animals identified as females were females, and only the larger females present in choruses may be reproductively mature.

Our results also have direct implications for researchers wishing to conduct experimental studies with the Mink Frog. We found that it was relatively challenging to acquire eggs and thus larvae for experimental purposes (~50 person hours in the field yielding four egg masses obtained prior to hatching). The most productive approach was to hand-capture breeding adults in the field (reaching out of a canoe and grabbing the animals being more effective than dip-nets) and to confine them to aquatic enclosures for oviposition observations. Even with this approach, it is unlikely that large numbers of egg masses can be obtained.

Acknowledgments.—We thank James Gibbs, Cathy Bevier, and Glenn Johnson for their help and support with this research, and two anonymous reviewers for greatly improving an initial draft of this manuscript. Funding support was provided by the Northeastern States Research Consortium. All research was conducted under the guidelines for Animal Care and Use provided by Paul Smith's College and with appropriate permits granted by the New York Department of Environmental Conservation.

Reducing Predation of Freshwater Turtle Nests with a Simple Electric Fence

The current vulnerability and widespread declines of nonmarine turtles are increasingly becoming a focus of conservation concern, adding to the decades-long attention paid to marine species (Gibbons et al. 2000). Various anthropogenic factors have increased the populations and ranges of certain medium-sized predators across much of North America (e.g., Larivière 2004; Oehler 1995). These changes are widely believed to have elevated turtle nest predation pressures and to have contributed to recent declines of many populations (Browne and Hecnar 2007; Garrott et al. 1993; Reynolds and Tapper 1996; Temple 1987).

While recognizing that ongoing efforts to reduce adult mortality will be essential for long-term turtle conservation success (e.g., Heppell 1998), turtles are limited in their ability to respond to increased mortality at any life stage, including the nest stage (e.g., Congdon et al. 1993). Lack of adequate recruitment causes changes in turtle community size and age structure (Jackson 1988; Rubin et al. 2004; Thompson 1983), sometimes to the point of species extirpation (e.g., Browne and Hecnar 2007). Thus, efforts to counter anthropogenic nest predation may augment overall conservation measures by enhancing recruitment of juveniles into local populations. As an alternative to currently practiced nest protection methods—largely nest screening—the present study investigated the nest protection potential of a novel electric predator exclusion fence designed to concurrently allow the safe and unhindered passage of almost all North American chelonians.

Methods

Site descriptions.—Two traditional turtle nesting areas were located using satellite imagery of the lower Wisconsin River corridor

(http://www.weather.com/weather/map/interactive/; accessed 25 October 2007) to remotely survey likely habitat, followed by on-site inspections to confirm previous nesting activity via destroyed nests. Both areas are on level terraces on the south bank of the Wisconsin River within 10 km of Spring Green, Sauk County, Wisconsin. Site A is 52 m from the river and is bordered by mesic to dry-mesic, open woodlands. Site B, 7.3 km distant from Site A, is 15 m from the river, adjacent to an open sand beach. Both sites have bunch grasses (primarily switchgrass, *Panicum virgatum*) and various low, xerophytic herbaceous plants (primarily peppergrass, *Lepidium* sp.) covering approximately 20% of the substrate, with the remainder being open sand.

Study design and implementation.—At each study site two treatment (fenced) and two control (unfenced) areas were designated in areas of similar apparent historical nesting concentration as indicated by remains of destroyed nests. For practicality, treatments were located within nesting areas such that their combined area could be enclosed by one fence. Controls, typically adjoining treatments, were chosen such that apparent nesting density, distance to nearest water, topography, and vegetational composition aspects were similar between control and treatment areas.

Each of the control and treatment areas was monitored by a separate trail camera (combinations of Reconyx Silent Image™ RM30 and Reconyx HC600 HyperFire™), with the sizes of both treatment and control areas delimited by the useful size of camera field of view (FOV): approximately 58 m² per camera. Treatment camera FOVs also included some area immediately external to fence peripheries. Cameras were mounted on poles in protective boxes at heights of approximately 2.5 m, topped with an inverted 10-cm-diameter plastic funnel, into which was inserted a sharpened dowel to discourage perching by American Crows (*Corvus brachyrhynchos*). Cameras were programmed to take continuous time-lapse (TL) images at one-minute intervals and sequential rapid-fire series when triggered by motion (MT).

Nest predation rates (calculated as the proportion of initial camera-documented nests excavated by aboveground predators from deposition through hatchling emergence) were compared between control and treatment areas. Nests excavated by predators during a given nest's emergence period that contained only non-predated eggshells upon inspection were conservatively designated as "fate unknown" because undocumented predation on pre-dispersed hatchlings may have occurred.

Fence description.—Fences incorporated one electrified wire (hereafter referred to as the "hot" wire) of 17-gauge fencing wire 25.4 cm above the substrate and two non-electrified strands of 4-mm-diameter, green vinyl clothesline (containing a wire core to reduce rabbit [Leporidae] damage) 15.2 cm and 20.3 cm above the substrate (Fig. 1). A solar-powered charger (Parmak DF-SP-LI, 1.4 joules) energized the top, electrified strand. Each fence enclosed approximately 72 m² with a 35-m perimeter.

Before fence installation, the perimeter was cleared of coarse vegetation by a metal garden rake, leveled as needed using a 91-cm length of lumber, and tamped by foot. A light wire fence (12-gauge, 71-cm-wide Red Brand® Poultry and Rabbit fence) was then laid on this prepared perimeter (hereafter referred to as the "screen ground") in order to provide an effective electrical ground. (The xeric sand and sandy loam substrates often used by nesting turtles are generally non-conductive.) The screen ground was rolled out with the smaller mesh to the outside such that it sprang up, not down, during installation to facilitate a closer attachment to the substrate and was secured

to the substrate with wire "staples," approximately 30 cm in length, made from coat-hanger wires bent into a narrow U-shape. Fencing wire was used to sew together adjoining pieces of the screen ground to ensure a continuous electrical ground connection. On occasion, broom sweeping or gently raising and lowering the screen ground was necessary to re-expose it after heavy rainfall.

Fences were constructed using standard metal support rods and plastic insulators and were positioned over the screen ground 36–41 cm in from the outside edge. Fencing rods were placed at varying distances (0.5–4.0 m) as required to maintain consistent ground-to-fence strand clearances. Rods at corners and significant bends in the perimeter were supported by standard metal T-posts using short loops of fencing wire to allow significant hand tensioning of the strands. Further tensioning was provided via a screwdriver placed into these loops and rotated (a restorative method also used in subsequent maintenance visits). The T-post at the terminus of the fence near the charger was also used as a tie-off for the rope strands. Both the fence and the screen ground were connected to a 2.5-m galvanized ground rod using insulated hook-up cable. Electric fence warning signs were attached to fencing rods, one on each side of the fence, using 12-mm binder clips.

The fence was baited with pouches 25 cm^2 in area made of folded 3-mm galvanized hardware cloth containing bait (dry, fish-flavored cat food or commercial skunk paste bait, i.e., "Grubstake;" Jameson's Ultra Blend, Daisytown, Pennsylvania, USA), and wrapped vertically with a 19-mm-wide strip of aluminum foil (serving as a potential visual attractant). The foil strips were wound around bait pouches such that approximately 2.5 cm of excess provided a sheltering roof suspended over the applied bait. The pouches containing cat food alternated with empty wire pouches with approximately 1.25 cm^3 of the paste bait applied to the foil wrapping under the overhanging flap (Fig. 1).

Pouches were attached to the hot wire by a short length of fencing wire routed 2.5 cm away from the fence rod at the top insulator to prevent shorting and threaded through outside holes (already present) in the three insulators holding the fence strands. Another insulator positioned immediately below these three, at 10 cm above the substrate, served as a backing for the bait pouch and prevented electrical shorting. Bait pouches were attached to the connecting leads using 12-mm binder clips at approximately 3- to 4-m intervals and positioned close to the outside surfaces of the backing insulators.

Study timelines and schedules.—Sites were monitored from 2009 through 2011, following a pilot study in 2008. In all years but 2010 the treatment fences were enabled and baited and all areas were camera-surveyed from 10 May through 10 October—a few weeks before anticipated nesting activity to beyond the end of the typical emergence period. June floods in 2008 and 2011 allowed for at least partial nest survival and continuance of site monitoring, whereas a mid-July 2010 flood caused the loss of all nests and early termination of monitoring activities.

Sites were visited 2–3 times a week to change camera data cards. Baits were changed out at two-week intervals, regardless of intervening weather. Vegetation was usually removed from the screen ground by hand weeding to ensure optimal fence grounding conditions and to prevent electrical shorting by strand/bait station contact. On the uncommon occasions when hand weeding was impractical, glyphosate herbicide (Round-Up®, Monsanto Co., St. Louis, Missouri) was applied to problem areas.

Results

Turtle use of study sites and interaction with fences.—Ouachita Map Turtles (*Graptemys ouachitensis*) (N = 70), along with one Northern Map Turtle (*G. geographica*) and other unidentifiable *Graptemys* (N = 27), made up the nesting community. *Graptemys* also made up 90% (N = 77) of the transient turtles (moving through, but not nesting on monitored areas) identified to species on the study sites along with Snapping Turtles (*Chelydra serpentina*; N = 6), softshells (*Apalone* spp.; N = 3), and unidentified transient turtles (N = 37), most or all of which likely were *G. ouachitensis*.

Turtles displayed no aversion to traveling under the fence strands, as evidenced by counts of nesting and transient females on control and treatment areas (79 individuals exclusively in controls vs. 142 with presence in treatments for all years and sites combined) and the lack of route-diverting behaviors noted (Fig. 2). In total, 39 and 59 nests were constructed in control and treatment areas, respectively, during the study period.

Predator community.—Both TL and MT image counts were used to generate site visitation frequency indices for each predator species for the full season years of 2009 and 2011 (10 May–10 October). A separation criterion of 0.5 h was used to designate separate on-site occurrences. Raccoons were the most common predator at both sites by a wide margin (Table 1) and were the only species documented to destroy turtle nests.

Effect of electric fence exclusion on nest predation rates.—The fence exclusion efficiency for each predator species was assessed using ratios of treatment versus control area image counts (as above, but with breaches counted as separate events regardless of intervening time; Table 1). Lower values thus indicate greater exclusion effectiveness.

The fences were successful in reducing predation rates on turtle nests (89% for 37 control nests vs. 15% for 53 treatment nests; one-tailed Fisher's exact test, $P < 0.001$ for all years and both sites combined (Table 2)—primarily by fence effectiveness in reducing nest-focused raccoon access to treatment areas (Table 1).

Interaction of predators with fences.—Images from both the study itself and from supplemental off-site tests show that raccoons generally approach and investigate fences rather deliberately, enhancing the potential for teaching shocks. The 15.2-cm lowest strand setting requires considerable body flexing of adult raccoons attempting breaches under the fence, motivating most individuals to eventually try an over-the-top entry. While some raccoons receive shocks at their first interaction with the fences, others have successful breaches over several days before effective contact with soft tissue or lightly furred areas is made.

Five observations of adult raccoons being shocked were via hand touch of the hot wire and three were via bait pouch contact. Additional instances of raccoons inspecting bait pouches (N = 10) but lacking images of consequent effects indicate that bait contact may have been responsible for many undocumented shocks. However, off-site tests using non-baited fences demonstrated complete raccoon exclusion within a few days of first encounters, showing that adult raccoon exclusion is possible without fence baiting. Dry cat food appeared at least as attractive to raccoons as commercial skunk paste bait (eight vs. four images of bait inspection, respectively).

Low-positioned baits were used in this study primarily as a possible breach deterrent for smaller predators such as subadult raccoons, skunks (*Mephitis mephitis*), and opossums (*Didelphis virginiana*) that would not be vulnerable to shock from

hot wires placed well above substrate level. However, skunks and opossums routinely breached the fences (Table 1), with limited documented interest in either cat food or commercial skunk bait as presented. Regardless, skunks and other small predators were not documented to depredate turtle nests during this study, even though surviving treatment and control nests were available at hatching time, when these predators were most often present on-site. (Two nests were excavated by skunks: one after the typical hatchling emergence interval [at 19 days; considered not depredated], and another at four days after first hatchling emergence [considered "fate unknown"]).

Although infrequent (mean 3.5 per year/site; Table 3), fence breaches by raccoons occurred in every study year. Chance variables, such as the number of recently constructed nests inside the fence at a given predator breach, can significantly influence the protection rate in a given year. For example, seven of the eight depredated treatment nests during this study were destroyed during a single breach event. Raccoons often travelled along fence perimeters, suggesting that they would quickly exploit any newly available opportunities for entry.

Estimated costs.— Approximated yearly fencing costs (amortized over a projected 15-year fence life) for various-sized exclosures are presented in Table 4. Fencing costs reflect the sum of fixed costs (e.g., solar fence charger units) and variable inputs that scale with perimeter length (e.g., fencing rods and bait stations). Fencing costs per unit area decrease with increasing area protected (Table 4), since expenses either remain the same (fixed costs) or increase linearly (variable costs), while the area enclosed increases exponentially. The number of theoretically protected nests is based on 75% nest protection efficiency—less than that realized in this study as a conservative measure—applied against a mean study nest density of approximately one nest per 9.3 m². Labor rates ($19.57/h) are based on the 2010 starting base wage and benefits rate for a Wildlife Technician, Wisconsin Department of Natural Resources.

Discussion

Management implications.—The overall increase in turtle nest survival (74 percentage points) via fence-reduced raccoon access to nests in this study compares well with the performance of electric fences that have been used to protect the nests of ground-nesting birds (e.g., mean 34 percentage points, range 16–64%, N = 8, from Table 1 in Jimenez et al. 2001). In contrast to the traditional use of electric fencing to enhance nest success of game species, its use involving turtles (and other reptiles) is

Based on a 25-week management period, 15-minute travel time for 1x week site visit, one minute to inspect 61 m of perimeter, and one minute to bait each station (based on field experience). See text for additional details.

relatively unexplored. As such, the development of a successful fence for this purpose appears unique in published literature and represents an addition to the currently small array of methods commonly used to protect turtle nests.

Electric fencing is frequently more cost effective than other methods for protecting nesting areas of various wildlife species (Jimenez et al. 2001). While it entails relatively high initial material costs, ongoing labor demands are relatively low (although paid labor remains the largest cost input by a considerable margin; Table 4). Additionally, materials costs can be amortized over several years, as turtles often use the same nesting areas year after year (e.g., Tucker 2001). Once fencing is installed, management is reduced to periodic fence inspections, low-level maintenance, and bi-weekly baiting, without the need to actively monitor turtle activity and search for nests several times a week (nest screening) or regularly trap and euthanize or translocate predators (predator removal).

Fencing also circumvents some of the potential detractors of turtle management common in alternate methods, including incomplete nest detection (e.g., Burger 1977; Burke et al. 2005; Nelson 2004) and potential disturbance of nesting females under nest screening (e.g., Burger 1977; Jackson and Walker 1997), and the possible ecosystem disruption (e.g., Barton and Roth 2007; Ratnaswamy et al. 1997; Ratnaswamy and Warren 1998; however, see Hecht and Nickerson 1999) and controversy (e.g., Hecht and Nickerson 1999) of predator control.

However, while the fences were effective overall, some of the breaches that did occur resulted in nest loss, suggesting the need for further context-dependent experimentation with strand arrays and baiting regimes. For example, lowering the bottom strand to 12.7 cm above the substrate may reduce under-the-fence breaches by raccoons while still allowing generally unimpeded turtle transit (including most Snapping Turtles; G. Geller, unpubl. data). In all situations the design should encourage over-the-fence predator breach attempts, rather than under—enhancing likelihood of hot wire contact with hands and other lightly furred areas—while still providing unhindered, safe passage of nesting turtles. Improvements seem particularly needed in the exclusion of skunks and other small predators, possibly by experimentation with different baits and bait replacement intervals. The possibility that non-baited fences would significantly exclude adult raccoons would reduce material and labor costs. However, the resultant potential for increased predation from young raccoons and other small predators without baiting is unknown and likely context-dependent.

The species composition of the local predator community, as well as the timing of their on-site presence, will influence protection results. For example, protection levels in this study may have been different if skunks had been commonly present during the nesting season *per se*, rather than later in the year as was found here. Likewise, predation by feral pigs (*Sus scrofa*), armadillos (*Dasypus novemcinctus*), foxes (e.g., *Vulpes vulpes*), Fish Crows (*Corvus ossifragus*) and other species (and size-differing geographical races) not encountered in this study may also produce different results, again prompting locally tailored modifications of the fencing scheme.

Implementation caveats.—Longer perimeters increase the chances for predator breaches due to increased chances for inconsistencies in strand height-to-substrate spacing, electrical shorting via fallen branches, etc., and thus require more attention to maintenance. Smaller, well-protected nesting areas are preferred to larger, less-protected ones, unless due stewardship can be ensured. In many cases it may be more productive to protect large nesting areas by using several smaller enclosures, all connected to one charger.

The positioning of the hot wire at 25.4 cm above the substrate in this fencing scheme greatly reduces the likelihood of electrical contact for all non-marine North American turtle species except Alligator Snapping Turtles (*Macrochelys temminckii*). It is thus important to employ this method only where the absence of this turtle (as well as marine species, Chelonioidea) can be reasonably expected given site history, or where effective approach-blocking mechanisms (e.g., size-filtering barrier fences) can be installed.

Acknowledgments.—I am grateful for generous philanthropy of S. Paust, D. and S. Caves, P. Geller, J. Rinehart, and the Madison Audubon Society, without which this effort could not have been undertaken. I am also indebted to landowners G. and C. Heck and W. and K. Schultz for granting me access to their properties. For productive communications on several fronts, I thank J. Dadisman, R. Engeman, B. Foat, R. Gatti, B. Hay, D. Kelleher, D. Klemm, P. Pritchard, N. Reindl, J. Suckow, S. Vantassel, R. Wheeler, and many others too numerous to mention. I especially thank S. Temple for his longtime support and guidance and the two anonymous reviewers who improved earlier versions of the manuscript. Finally, I wish to express my gratitude to my family for their enduring patience and encouragement.

Predation on Spotted Salamanders (*Ambystoma maculatum*) by the Red-shouldered Hawk (*Buteo lineatus*)

Snakes and mammals are commonly suggested predators of metamorphic and adult ambystomatid salamanders (e.g., Beneski et al. 1986; Ferguson 1961; Huheey and Stupka 1967; Liner 1954; Madison 1997; Nussbaum et al. 1983), although direct evidence is often lacking. The limited data are not surprising because mole salamanders occupy tunnels in the forest litter for all except a few days of the year during the breeding season. Information for the Spotted Salamander, *Ambystoma maculatum*, is no exception, and despite radio tracking of animals into the tunnel systems, just a few cases of predation by shrews (*Blarina)*, garter snakes (*Thamnophis*), and weasels (*Mustela*) have been recorded (Madison 1997).

Among potential avian predators of adult ambystomatid salamanders during the breeding season are owls and hawks (Errington and Breckenridge 1938; Granzinolli and Motta 2007; York et al. 2002). The Red-shouldered Hawk, *Buteo lineatus*, may be a frequent predator because it favors deciduous woodlands and flood plain forests (Dykstra et al. 2008; Portnoy and Dodge 1979; Scheffers et al. 2006), which are also favored by ambystomatid salamanders (Petranka 1998). The two species also begin breeding activity in early spring when many other potential prey of raptors (e.g., snakes, toads, frogs, many song birds) are not yet available, or like the meadow vole, *Microtus pennsylvanicus*, are at post-winter population lows (Taitt and Krebs 1985).

Reports of Red-shouldered Hawk predation on salamanders exist (Ernst 1945; Errington and Breckenridge 1938; Howell and Chapman 1998; Rathburn and Murphy 1996; Scheffers et al. 2006; Stewart 1949), but no study specifically reports that ambystomatid or any other salamander species may at times be prominent in the diet of this hawk species. This contrasts with reports of frog species having the greatest biomass in the pellets of the Red-shouldered Hawk (e.g., Howell and Chapman 1998). Here we report evidence of the yearly exploitation of a local breeding population of Spotted Salamanders by the Red-shouldered Hawk.

Methods.—We made observations at a private, woodland residence 8 km E of Ithaca, Tompkins Co., New York, USA (42.7°N, 76.85°W) from late March to early May 2006–2009. We placed a Swarovski™ ST80 (20x–60x) telescope inside a window of an isolated residence overlooking a 380 m^2 man-made, fishless pond, which began 10 m S of the residence. The pond was constructed in 2000 with a steep bank and a plastic liner. The steepness of the sides and the depth of 4 m at the center are not favorable for the growth of aquatic plants, yet several amphibian species readily adopted the pond for breeding. Our vantage point allowed identification of vertebrate prey captured and eaten by a Red-shouldered Hawk as it perched on various objects around the pond, including the roofs of three 1.6 m high bird nest boxes about 4 m from the pond edge. Mixed northern woodlands (beech/birch/maple/oak/hemlock), typical throughout the region, immediately surrounded the house and pond.

Observations in all four years began near the end of ice melt in March with the disappearance of the earlier breeding Jefferson's Salamander (*Ambystoma jeffersonianum*) and the concurrent appearance of breeding Spotted Salamanders (adults 15–25 cm total length; 14–33 g; Bishop 1941) and at least one Red-shouldered Hawk (referred to as RSHA). We believe the same individual hawk was responsible for all the observations because we noticed a unique patch of white feathers on its face whenever we had a frontal view of the hawk and were not focusing on other predation details. In addition, we never observed more than one Red-shouldered Hawk at the pond at a time. We will present the data as if only one hawk was involved, but we cannot say this for certain. We ended observations in early May when Spotted Salamanders and RSHA were no longer observed. We scanned the pond frequently weekdays between 0645 to 0830 h and after 1830 h, and on some weekends at various times throughout the day. During 2006, the number of foraging attempts and successful kills was not documented, but predation was observed on several

occasions, and abandoned carcasses were collected and frozen for later identification. During 2007–2009, we left prey carcasses in the field, but documented the dates and times of foraging activity. Recordings began whenever the hawk was first noticed at the pond, sometimes perched on a nest box, sometimes transporting a kill, and sometimes eating a captured prey at a perch.

Results.—In the 2006 breeding season, we observed numerous predation events, photographed one (Fig. 1), and retrieved six abandoned carcasses from the tops of the nest boxes, all of which were Spotted Salamanders (Table 1). Two carcasses consisted of just the tail, three included the pelvic girdle along with the tail, and one had just the head removed. Swollen egg masses were occasionally observed on top of the nest boxes along with carcasses indicating that some prey were gravid females. As the eggs require water to swell up, these females were probably taken from the pond surface because water was only observed to drain off the legs of RSHA (onto the tops of the nest boxes and any exposed eggs) after pond surface attacks.

RSHA foraging and predation attempts were recorded continuously for 3 to 84 minutes during 1.8 h of observation in 2007, 6.3 hrs in 2008, and 0.3 hrs in 2009, with recording sessions beginning when RSHA was noticed at the pond (Table 1). Successful predation by RSHA on Spotted Salamanders was observed, but not documented, during the same salamander breeding period prior to 2006 and in 2010. In 2011, RSHA was not observed during the spring breeding period, but an unidentified Red-shouldered Hawk was observed eating frogs at the pond in early June of 2011 after adult *A. maculatum* had emigrated.

During the 15 days RSHA was seen at the pond from 2007 to 2009, we recorded 8.4 h of foraging activity during which RSHA was seen perched 39 times on various objects around the pond and made 35 descents to the ground or water surface in an attempt to capture prey or to feed on previously captured prey. Descents included 12 instances of swooping down and breaking the pond surface with the talons and lower legs, 19 attempts to capture prey at various locations on the ground (grass, pond bank), and 4 successful attacks when the observer did not record the strike location but recorded prey retrieval and consumption (Table 1). Included in the 19 known ground attacks were several instances where, upon landing, RSHA would search through leaves or 0.03 m high grass or reeds at the pond edge for a few seconds to two minutes until the prey was found. One of the 12 known pond surface attacks was successful, while 13 of the 19 known ground attacks were successful (Table 1). Of the 24 prey recorded over the four years, 20 were *A. maculatum*, three were ranid frogs, and one was a small mammal ("a mouse"). Of the 14 Spotted Salamanders observed killed in 2007–2009, 10 were eaten whole or in part at the pond with any remains being abandoned (Table 1). Of these 10, 3 were completely eaten, and 7 were eaten to various degrees down to the pelvic girdle (similar to the six partial carcasses collected in 2006). Of the 4 remaining *A. maculatum* kills, one was eaten in the grass without identification of the body parts consumed, one was carried away without being eaten at the pond, and two were partially eaten before being carried away. Those carried away were captured 19 March, and 4 and 7 April, before *B. lineatus eggs* hatch in New York State (Crocoll and Parker 1989). We had no evidence of RSHA transporting or eating egg masses, although some eggs may have been eaten when RSHA fed on gravid females.

On 6 April 2008, another observer in a bird blind monitored the pond from 0900 to 1000 h and observed six unsuccessful water surface attempts by RSHA, probably directed at Spotted Salamanders because these were the only animals noticed at that time (we frequently noted them surfacing from the depths in the clear pond water, presumably to gulp air).

Discussion.—Our observations of the Red-shouldered Hawk foraging around a small, man-made pond supporting an amphibian breeding population indicated that (1) the Red-shouldered Hawk killed and ate mostly *A. maculatum* at the site at the time of the study, (2) the anterior portion of the body of *A. maculatum* was preferred, and (3) foraging by the hawk was more successful on land-based prey than prey at the pond surface.

Factors that may have facilitated RSHA predation on Spotted salamanders at our study pond were the scarcity of pond vegetation and the depth of the pond. The scarcity of plants and fallen branches could have forced salamanders to be more exposed at the pond edge or to retreat to deeper water from which they had to surface frequently to gulp air because of possible anoxic conditions and the failure of cutaneous respiration to provide adequate oxygen in recently ice-covered, winter/spring ponds (Barcia and Mathias 1979). Both of these conditions would make the salamanders more vulnerable to hawk predation during the day.

Predator avoidance of the posterior body parts of *A. maculatum* has also been reported by Beachy (1991), who identified just the tail and pelvic girdle of 21 *A. maculatum* carcasses around a breeding pool in North Carolina. The avoidance of posterior body parts is consistent with toxic skin glands in this and other salamander species, particularly in the tail (Barach 1951; Brodie 1971; Brodie et al. 1979; Howard 1971). Eating few toxic prey, or the less-toxic portions of prey, are counter strategies of predators and herbivores to chemical defenses in their food (e.g., Karban and Agrawal 2002). Eating just the non-toxic portions of prey could easily increase the number of prey needed for food by the hawk, and concurrently increase the hawk's impact on the local *A. maculatum* breeding population. Because RSHA ate the entire salamander in 3 of the 10 observed eating events, our observations suggest that RSHA moderated its consumption of a moderately toxic defense chemical.

The greater success of prey capture on land than from the pond surface is consistent with the higher frequency of *A. maculatum* captures during the start of the post-breeding emigration when spotted salamanders take up temporary refuge in pond edge refuges (Madison 1997), as was apparent in the grass/reeds of our study pond. It is also consistent with mostly terrestrial prey in the diet of *B. lineatus* (Dykstra et al. 2008).

Acknowledgments.—We thank Marie Read (www.marieread.com) for helping with mid-day observations and for photographing a hawk kill, and Victor Lamoureux for reviewing the manuscript.

Survival Blood Sampling in Small Frogs Using "Keyhole Cardiac Puncture"

As research animals, frogs are notoriously hard to collect blood from, particularly when compared to their mammalian counterparts. Studies relating to osmoregulation and water balance in amphibians frequently require the analysis of body fluids, as do studies on stress responses, exercise physiology, immune function, and freezing tolerance. Double-pithing followed by blood extraction from the heart is a common but lethal technique (Costanzo and Lee 2008; Edwards et al. 2000; Irwin and Lee 2003). Some workers obtain blood from major blood vessels like the ventral abdominal vein, the inguinal vein, or the femoral artery (Busk et al. 2000; Wright and Whitaker 2001; Zimmerman et al. 2007), from the orbital sinus (Lynch and Wilczynski 2008), or collect lymph (Reynolds et al. 2009). However, the most commonly used non-lethal method used to sample blood from larger (> 20 g) anurans has been standard percutaneous cardiac puncture (Daló et al. 2007; Tyler 1999; Wright and Whitaker 2001). Percutaneous cardiac puncture involves inserting a needle through the chest wall to withdraw blood from the ventricle. However, a number of problems can arise when using this method to sample blood from smaller anurans (body length < 5 cm; weight < 10 g). Due to its small size, the heart can be hard to locate with a needle, particularly since the position of the ventricle can vary relative to external landmarks (Tyler 1999), increasing the risk of inadvertent damage to other organs. Needles are dulled if the heart is not located on the first attempt, making the heart harder to puncture. The blood volumes that can be obtained from small anurans using percutaneous cardiac puncture often vary substantially and may be contaminated by lymph or other tissues (Rexer-Huber 2009; Wright and Whitaker 2001). The probability of failing to obtain any blood when using percutaneous cardiac puncture appears relatively high and may be affected by treatments that decrease heart rate/blood flow such as anaesthetic use or cold exposure (Cakir and Strauch 2005; Maniero and Carey 1997).

It is therefore unsurprising that smaller anurans (< 5 cm and/or < 10 g) are often killed to obtain blood volumes sufficient for analysis (Edwards et al. 2000; Jenkins and Swanson 2005; Marler and Ryan 1996). However, terminal blood sampling is frequently not ideal, for example if sequential sampling is required, and may not be possible in small populations and/or endangered anuran species. We developed a nonlethal procedure for blood sampling from small anurans with the aim to minimize the risk of serious injury without causing unnecessary stress to animals. The study species *Litoria ewingii* Duméril and Bibron 1841 is a small frog species (adult length 3–5 cm, weight 1.5–7 g; Rexer-Huber 2009) of the family Hylidae, native to southern Australia and introduced to New Zealand.

The aim of this study was to develop a method to sample blood from small anurans that is easy to perform, reliable in terms of quantity and quality, and survivable. Here, we report on anaesthesia induction and recovery and describe the details of obtaining blood by keyhole cardiac puncture (k.c.p.) in *L. ewingii*.

Methods

Animal collection and housing.—Litoria ewingii (N = 75) were wild-collected from around ephemeral ponds in Central Otago, New Zealand. Life history stages from recently metamorphosed to mature adult were included, with frog body weight 1.37 ± 0.2 g (mean ± s.e.m.) and snout–vent length (SVL) 2.13 ± 0.09 cm. Adult *L. ewingii* weighed 1.02–7.39 g (SVL 2.21–4.93 cm), while juveniles weighed 0.53–1.00 g (SVL 1.82–2.42 cm). Metamorphs weighed 0.33–0.48g (SVL 1.51–1.81 cm). Within 5 h of collection, frogs were transferred to a well-ventilated 20°C incubator (MTR-153, Sanyo Electric, Japan) at 80–90% humidity and a 12:12 h light:dark photoregime, and sampled as soon as possible. *L. ewingii* were not acclimated to standard conditions before the study, since the aim of this study was to assess the utility of k.c.p. in field acclimatized frogs.

Following sampling, frogs recovered in individual plastic vivaria (10 x 11 cm height x diameter; 19–22°C, 12:12 h light:dark, 80–90% humidity) on damp paper towels, and were fed with

Drosophila and small locusts *Locusta migratoria* every second day. Because immune parameters recover from cardiac blood-sampling within a week (Maniero and Carey 1997), frogs were moved into group vivaria (35 x 23 x 22 cm length x width x height) one week post-sampling. Group tanks contained vegetation, stones and small ponds of filtered aged tap water and housed a maximum of five adult or eight juvenile *L. ewingii*. Frogs were fed weekly with *Drosophila*, locusts and houseflies *Musca domestica*.
